OSMOTIC PRESSURES OF CONCENTRATED SOLUTIONS

BY WILDER D. BANCROFT AND HERBERT L. DAVIS

Introduction

Probably the largest single contribution to the theory of solutions was made by van't Hoff in his papers,¹ in which he elaborated the analogy between osmotic pressure and gas pressure. Many articles have since appeared as extensions of or deductions from the generalizations there enunciated; but it seems that the most fundamental relation, that between osmotic pressure and the vapor pressure of a solution, was not stated very clearly by van't Hoff nor understood thoroughly by those who have worked on such problems since. Several authors have indeed given fairly complete and accurate statements of the van't Hoff equations; but so many more have erred in applying them or their simplifications and extensions to actual data that it appears desirable to derive the equations again, and to point out some useful applications of them.

It may be made clear that this paper will not deal with the vexed question of what the nature of osmotic pressure is, nor to what it is due. Those interested may find a very interesting discussion of that in the Transactions of the Faraday Society for June, 1918 vol. 13, pp. 119-189. For our purpose, it will be sufficient to follow van't Hoff.²

In order clearly to realize the quantity referred to as osmotic pressure, imagine a vessel, A, completely full of an aqueous solution of sugar, placed in contact with a vessel B. If it be conceived that the solid walls of this vessel are permeable to water but impermeable to the dissolved sugar, then, owing to the attraction of the solution for water, water will enter the vessel A up to a certain limit, thereby increasing the pressure on the walls of the vessel. Equilibrium then ensues, owing to the pressure resisting further entry of water. This pressure we have termed *osmotic pressure*."

There are two forms of the equation connecting osmotic pressure and vapor pressures that may be deduced by the aid of the reversible cycle of transformations so useful to van't Hoff. Certain assumptions which will be introduced into the derivation will be stated as need for them arises. Subject to these well-recognized and easily evaluated limitations, the equations derived are absolutely accurate and general.

Derivation of Form I.

We may imagine the solution in a cylinder fitted with a piston permeable to the solvent but not to the solute. The system is at constant temperature.

1. The piston is pushed in far enough to squeeze out one gram of solvent from so large a volume of solution that the concentration change produced

¹ Z. physik. Chem., 1, 481 (1887); Kongl. svenska Vetenskaps Akademiens Handlingar, 21, 3 (1885); Phil. Mag., (5) 26, 81 (1888).

² Phil. Mag., (5) 26, 81 (1888).

shall be negligible. By taking a sufficiently large amount of the solution, ten million liters for example, the error introduced by this, the first assumption, can be made as small as one pleases. In pressing out this gram of solvent, the piston must move through V_g , the volume of one gram of the solvent in the solution and against the osmotic pressure P of the solution. The work done then will be:

$$W_1 = PV_g$$

work done on the system being called positive.

2. This gram of solvent may then be vaporized at its own vapor pressure. The second assumption here introduced is that the volume of solvent as liquid is negligible in comparison with its volume as vapor at the same temperature. At ordinary temperatures, one can usually ignore the error here introduced which is of the order of one part in four thousand for water at 25°C ; but which becomes very large as one approaches the critical temperature. In accordance with this, then

$$W_2 = - \frac{p_0 v_0}{M_2}$$

where p_0 and v_0 are the vapor pressure of the pure solvent and its mol vol at that pressure, and M_2 is the molecular weight of the solvent in the and not the liquid.

3. The gram of solvent vapor is then permitted to expand from the pressure of the pure solvent (p_0) to the vapor pressure of the solution. Here is introduced the third and last assumption,—that the vapor of the solvent follows the gas laws. This introduces very little error for most solvents although, of course, acetic acid is barred, because its molecular weight in vapor is a function of the pressure. If $p v = RT$, we get by differentiating $v dp + p dv = 0$ and $v dp = -p dv$. Also $v = RT/p$, whence $v dp = -RT dp/p$. The work done in this step will be

$$\begin{aligned} W_3 &= - \frac{1}{M_2} \int_{v_0}^{v_1} p dv \\ &= + \frac{1}{M_2} \int_{p_0}^{p_1} v dp = - \frac{1}{M_2} \int_{p_1}^{p_0} RT \frac{dp}{p} \\ &= - \frac{RT}{M_2} \ln \frac{p_0}{p_1} \end{aligned}$$

In this derivation v_1 is the volume of one mol of solvent vapor under pressure p_1 , the vapor pressure of the solution.

4. The gram of solvent vapor at pressure p_1 and occupying volume v_1 is condensed reversibly into the solution and the work done is

$$W_4 = \frac{p_1 v_1}{M_2}$$

According to the second law of thermodynamics, the resultant work produced by such a reversible, isothermal, cycle must be zero.

$$W_1 + W_2 + W_3 + W_4 = 0$$

or

$$PV_g - \frac{p_0 v_0}{M_2} - \frac{RT}{M_2} \ln \frac{p_0}{p_1} + \frac{p_1 v_1}{M_2} = 0;$$

$$P = \pm D_0 RT \ln \frac{p_0}{p_1}$$

where D_0 is the density of the pure solvent. They express the work done in changing unit mass of vapor from p_0 to p_1 as $RT \ln (p_0/p_1)$; but this will be true only if unit mass be a gram molecular weight of the vapor, for this value only is associated with R , the gas constant. This will be clear from step three in the present derivation.

Van Laar¹ derived Form I and also introduced an approximation which will be discussed later, and which was adopted and used by Frazer and Myrick (1916). Ewan² also gives Form I as having been first derived by van't Hoff and then by several other authors.

Porter³ made a very careful deduction similar to the one here presented, but introducing in addition correcting factors for the effect of pressure on the volumes and pressures involved. The exact equation derived by Porter consists of three integrals and is consequently not so immediately useful as the forms here given. He too presses out one gram of solvent and his resultant equation, after certain simplifying assumptions are made, is approximately

$$P_s = RT \ln \frac{p_0}{p_1},$$

in which s is the reduction in volume of solution when one gram of solvent escapes—that is V_g as we have defined it. In this equation also, there is no term for the molecular weight of the solvent.

Callendar⁴ shared in this general development, considering somewhat the question of hydration of the solute. Findlay⁵ reviews the whole problem quite thoroughly, but seems to regard the so-called thermodynamic equation (Form I of the present paper) as not immediately useful or at least useful only for the ideal solutions which will be discussed later. Kendall⁶ gives a most interesting discussion of Form I, calling it "the dilute-solution equation." He seems to exhibit a better comprehension of the equation and its real meaning than most authors who have touched on it. He points out clearly why it is useless for the calculation of solvent association. Mellor⁷ discusses osmotic pressure at length but does not give the form derived here. The nearest approach to it is

$$P + \frac{\alpha P^2}{2} = - \frac{RT}{V_0} \log (1 - N'),$$

which will be shown later to involve the assumption of an ideal solution. In this equation α is the compressibility factor of the solvent, N' is the mol fraction of the solute and V_0 is the mol volume of the solvent.

At various times, Frazer has dealt with the question of osmotic pressure and in a recent chapter¹ presents a derivation similar to the one used here and comes out with

$$P = \frac{RT}{v_0} \ln \frac{p_0}{p_1},$$

in which v_0 is the molal volume of the solvent in the solution, and consequently V_m as used here, provided that the molecular weight used in calculating v_0 be the molecular weight of the solvent as vapor and not in the solution. Frazer does not mention this point although it certainly enters in aqueous solutions, the osmotic pressures of which he has measured so well. However, in most of his work he assumes an ideal solution for which the molecular weight in the vapor must be the same as in the solution. W. C. McC. Lewis² derives Form I using slightly different notation and is quite clear that the molecular weight of the solvent as vapor is to be introduced.

The general expression connecting osmotic pressure and vapor pressure of a solution is then our Form I,

$$PV_m = RT \ln \frac{p_0}{p_1}.$$

It will be well to observe that in this expression there is no term for the concentration of the solution, only the vapor pressures of the solvent and solution, the temperatures and the value of V_m being needed for the calculation of the osmotic pressure. Also, as Kendall³ points out, the expression can have no value in indicating the extent of association of the solvent. Attempts have been made in vain to determine by its aid the existence of, or the extent of, association of water in aqueous solution. The molecular weight introduced must be the molecular weight of the solvent in the vapor state and most solvent vapors are not associated regardless of their condition in the liquid state or in the solution. An interesting exception to this is the case of acetic acid as solvent which Raoult and Recoura⁴ found to give quite abnormal vapor pressures lowerings on addition of solutes which in other solvents were normal. Raoult calculated his mol fractions from the molecular weight of the substances in the solution. Consequently he concluded that this abnormal lowering of the vapor pressure indicated that the apparent molecular weight of acetic acid in the solution was about 97 instead of the formula weight, 60. The apparent abnormality was explained by van't Hoff, who, in a note to the Raoult and Recoura paper, showed again that the molecular weight of the solvent *in the vapor phase* should have been introduced into the calculations. The molecular weight of acetic acid vapor was known to be about 118 when this value was used instead of 60, acetic acid was found to follow the law of vapor pressure lowering as did the other solvents. This will be discussed more at length later in the paper.

³ 1391 (1921).

⁴ 1890).

Derivation of Form II

There is another form of the osmotic pressure vapor pressure relation which may be derived as was the first, and which involves the same assumptions.

1. In this derivation, the semipermeable piston is pushed in far enough to squeeze out from the solution the number of grams of solvent in which one molecular weight of the solute is dissolved. The work done is

$$W_1 = PV_1,$$

in which P is the osmotic pressure and V_1 is the volume in the solution of that mass of the solvent in which one molecular weight of the solute is dissolved.

2. If the original solution contained g_1 grams of solute to g_2 grams of the solvent, there will be $\frac{g_2 M_1}{g_1}$ grams of the solvent squeezed out or $\frac{g_2 M_1}{g_1 M_2}$ mols of solvent squeezed out, where M_1 is the molecular weight of the solute in the solution and M_2 is the molecular weight of the solvent in the vapor. The work done in evaporating this mass of solvent at its own vapor pressure will be

$$W_2 = - \frac{g_2 M_1}{g_1 M_2} p_0 v_0,$$

where p_0 is the vapor pressure of the pure solvent and v_0 is the volume of one mol of solvent vapor under a pressure of p_0 .

3. This solvent vapor at p_0 is expanded to p_1 , the vapor pressure of the solution, and, by the same processes as were employed in the first derivation, the work term is

$$W_3 = - \frac{g_2 M_1}{g_1 M_2} RT \ln \frac{p_0}{p_1}.$$

4. Condensing the vapor, at pressure p_1 and corresponding v_1 , into the solution gives

$$W_4 = \frac{g_2 M_1}{g_1 M_2} p_1 v_1.$$

As before, the sum of the work terms must equal zero.

$$PV_1 - \frac{g_2 M_1}{g_1 M_2} p_0 v_0 - \frac{g_2 M_1}{g_1 M_2} RT \ln \frac{p_0}{p_1} + \frac{g_2 M_1}{g_1 M_2} p_1 v_1 = 0,$$

from which

$$PV_1 = \frac{g_2 M_1}{g_1 M_2} RT \ln \frac{p_0}{p_1}.$$

Since $\frac{g_1}{M_1} = n$, the number of mols of solute in the solution, and $\frac{g_2}{M_2}$ the number of mols the solvent would produce if converted into vapor, write

$$PV_1 = \frac{N}{n} RT \ln \frac{p_0}{p_1}$$

This equation will here after be referred to as Form

This relation is also to be found in van't Hoff's¹ paper when he derived the relation between concentration and vapor pressure lowering for a very dilute π percent sugar solution substantially as follows:

1. Remove, by the use of a cylinder with semipermeable wall, a portion of the solvent containing a kilogram-molecule (M_1) of the dissolved substance; here the total quantity of solution is supposed to be so great that no alteration of concentration occurs, and the expenditure of work is therefore RT .

2. This quantity, $\frac{100M_1}{\pi}$ kilograms, of the solvent is returned as vapor;

it may be conceived as produced from the liquid by evaporation at its vapor pressure; then expanded until its pressure is equal to the vapor pressure of the solution; and finally liquefied in contact with the solution. The kilogram-molecule of the solvent will thus receive an expenditure of work of $RT\Delta$,

where Δ represents the relative diminution of pressure; and the $\frac{100M_1}{\pi}$ kilograms will receive $RT\Delta \frac{100M_1}{\pi M_2}$. Here $\frac{\Delta M_1}{\pi}$ is Raoult's molecular diminution of pressure, which we shall term K ; employing this abbreviation, the expression becomes $\frac{100RTK}{M_2}$.

In a note to the Raoult and Recoura paper in 1890 van't Hoff extended this derivation and made it completely accurate. "In the change of vapor pressure from p_0 to p_1 , if normal densities exist, there is an energy increase of $RT \ln \frac{p_0}{p_1}$, which for dilute solutions where p_1 differs little from p_0 , becomes

$$RT \frac{p_0 - p_1}{p_0}."$$

This ratio, $\frac{p_0 - p_1}{p_0}$, is the relative vapor pressure lowering which he previously represented by Δ , and which now is accurately stated should be $\ln \frac{p_0}{p_1}$. We may now combine the first step of the earlier paper with the corrected value of the second work term in the later paper.

$$PV_I = RT \Delta \frac{100M_1}{\pi M_2}$$

in this equation $100 = g_2$, $\pi = g_1$ and Δ should be replaced by $\ln \frac{p_0}{p_1}$. Making

substitutions and omitting the simplifying approximations van't Hoff used, we arrive at the relation previously derived as Form II,

$$PV_I = RT \frac{N}{n} \ln \frac{p_0}{p_1} \quad (\text{II})$$

The relation between the two forms here derived for the same solution may be shown as follows

$$PV_m = RT \ln \frac{p_0}{p_1} \quad (I)$$

$$PV_I = RT \frac{N}{n} \ln \frac{p_0}{p_1} \quad (II)$$

Dividing, $V_m/V_I = n/N$ or in general $nV_I = NV_m$ which in words merely says that the volume, V_I , of the solvent in a solution for which $n = 1$ is equal to the mols of solvent present multiplied by the mol volume of the solvent in the solution, the mols present and mol volume of the solvent being calculated on the basis of its molecular weight in the vapor. Since this is, of course, obvious, the equivalence of the two forms is established.

Although Form II appears more useful than Form I, very little work has been done with it. Bancroft¹ gave Form II as having been derived from van't Hoff and went on to show that, if there is an evolution of heat on dilution, the osmotic pressure of the solutions would be larger than that called for by the formula and similarly the lowering of the freezing point of such a solution will be greater than when the heat of dilution is zero.

Before leaving the derivations, it might be well to point out that these equations are perfectly general and are accurate except for the assumptions definitely stated and easily evaluated. Up to the third work term in each equation, the only assumption introduced is that the volume of the solvent as a liquid may be neglected in comparison with its volume as a vapor. This assumption involves only a small, readily calculated, error, and, if it is desired, we may from step three take:

$$PV_g = \frac{1}{M_2} \int_{v_0}^{v_1} p dv$$

which involves only this single assumption and is free from the assumption that the vapor of the solvent follows the gas laws. This form is therefore more accurate than Form I as above derived, but is not so useful.

Possibly the work done in the four steps employed in the above derivations may be represented by a parallelogram such as is here shown:

In the derivation of Form I, one gram of solvent is pressed out of the solution and then returned to it; in Form II, that mass of the solvent in which one mol of solute is dissolved is put through the same cycle. This cycle con-

sists of the four steps as shown: first, pressing it out of the solution; second, vaporizing the solvent at its vapor pressure as a pure liquid; third, permitting it to expand to the vapor pressure of the solution; and finally, condensing it back into the solution. It may be mentioned that the V_1 of Form II contains N/n mols of the solvent, the N always being calculated from the molecular weight of the solvent in the vapor state. In both cases, work terms 2 and 4 are equal and opposite and therefore, the work done in step 1 equals that done in step 3. The cycle is represented by a rectangle for convenience but any parallelogram would serve equally well.

The Use of $PV = RT$ to express Osmotic Pressures

For most chemists, the most interesting item in the original papers of van't Hoff embodying the essentials of the above derivations was not the derivations but was the analogy which he showed to exist between osmotic pressure and gas pressure. This analogy was expressed as follows:¹

"The well-known formula expressing both Boyle's and Gay-Lussac's laws for gases

$$P V = R T$$

are, in so far as these laws are applicable to liquids also applicable as regards osmotic pressure; with the reservation also made in the case of gases, that the space occupied by the molecules must be so great that the actual volume of the molecules becomes negligible."

This limitation however was supplementary to an earlier one stated fully by van't Hoff and discussed at length by Ewan.²

"In 1885 van't Hoff showed that the equation

$$P V = R T$$

which expressed the relation between pressures, temperatures, and volume of a perfect gas, is likewise applicable to the osmotic pressure of a solution. Nevertheless, the behavior of most solutions is not strictly in accord with this equation and the present paper considers certain factors which are not represented in the simple equation $PV = RT$ and thus produces a formulation which is nearer the truth.

"The most important of these factors is, as van't Hoff observed, the heat of dilution of the solution. He says,³ after he has shown that the equation $PV = RT$ is as valid for solutions as for gases; 'Here the same reservations apply as in the case of gases, and the analogy between the two states of matter is such that the reason for the limitation is exactly the same in the two cases. We know that in the case of gases, deviations appear as soon as the concentration of the gas is such that the mutual attraction of the molecules is no longer negligible. By the same reasoning, the laws deduced for solutions can no longer be accepted in such circumstances. We may add that, in the

¹ Phil. Mag., (5) 26, 90 (1888).

² Z. physik Chem., 14, 409 (1894).

³ Kongl. svenska Vetenskaps Akademiens Handlingar, 21, 12 (1885).

case of solutions, this mutual effect of the solute particles on each other is easily observed; during the process of dilution, this effect gives rise to the production of internal work terms which are manifested in their thermal equivalents. Consequently the laws here derived apply to those solutions so dilute that the heat of dilution becomes negligible'."

Ewan then continues:

"By taking into account heat of dilution and the volume changes that appear on dilution, I have obtained certain equations for the relation between osmotic pressure, temperature, volume and heat of dilution which are so constructed that, when the heat of dilution and the volume changes are zero, the equations become identical with those derived by van't Hoff."

By means of equations then developed, Ewan was able to calculate the vapor pressures of some sulphuric acid solutions from the freezing points and heats of dilution. Ewan dealt with the quantitative conversion of the heat of dilution into work at the changing temperatures of the freezing points. Neither he nor anyone else has yet evaluated the heat of dilution at constant temperature as a work term. Until this is done, no simple equation of the form, $PV = RT$ plus or minus some work term, can be derived for the calculation of osmotic pressures. The equations here developed as Forms I and II are perfectly general and need no further correcting factors of any sort to express osmotic pressures.

Since these factors were difficult to evaluate and of less real interest than the fundamental relation, much of the subsequent theoretical development has been along the line of the ideal solution and this will be discussed at this point in order to make clear some references that have preceded this and many that follow. The concept of ideal solutions was introduced to obviate the necessity of introducing the heat of dilution.

Ewan¹ himself, five years after the above paper was published, gave what was probably the first definition of an ideal solution as: "an ideal solution is distinguished by the facts that no heat is evolved or absorbed and no change of volume occurs when it is diluted."

Several authors since have dealt with ideal solutions including especially G. N. Lewis and Hildebrand² who, in his recent monograph, says: "We may, therefore, follow G. N. Lewis in defining an ideal solution as one which obeys Raoult's law

$$\frac{p_0 - p_1}{p_0} = \frac{n}{N + n}$$

at all concentrations and pressures, a definition which has some important consequences. It follows from it, as Lewis has shown, that the formation of such a solution will take place from its component liquids without any heat of mixing and without any change in volume."

Washburn³ expresses the same relation in a slightly different form $p_A = p_{0A}X_A$, defining the terms in the statement: "The partial pressure

¹ Z. physik Chem., **31**, 22 (1899).

² "Solubility", 59 (1924).

³ "Principles of Physical Chemistry", 144 (1915).

of any molecular species above an ideal solution is equal to its vapor pressure as a pure liquid multiplied by its molecular fraction in the solution. In other words, the partial vapor pressure of any molecular species from an ideal solution is a linear function of its molecular fraction in that solution."

At this point, it might be well to add one more characteristic of the ideal solution which, although it is not always introduced into the discussion, may be of more fundamental importance than the others mentioned. If we generalize the ideal solution equation to avoid the confusion of solute and solvent using the definition of an ideal solution as just given, the relation may be written:

$$p_A = p_{0A} \frac{N_A}{N_A + N_B}$$

where N_A represents the number of mols of A dissolving in N_B mols of B and where p_A is the partial pressure of A over the solution and p_{0A} the partial pressure of pure A. For the dilute solution when N_A is small compared with N_B , this may be come:

$$p_A = p_{0A} \frac{N_A}{N_B}$$

$$\text{But } N_B = \frac{\text{volume of B used}}{\text{molecular vol. of B}} = \frac{V}{(M.V.)_B}$$

and consequently

$$p_A = p_{0A} (M.V.)_B \frac{N_A}{V_B}$$

For definite pairs of substances A and B, the values of p_{0A} and $(M.V.)_B$ are constants over the whole range of solubility. Therefore, we may write

$$p^A = K \frac{N_A}{V_B}$$

where, it is emphasized $K = p_{0A} (M.V.)_B$ and so is at once calculable for a given solution. But $p_A = K \frac{N_A}{V_B}$ is similar to the general form of Henry's law

which is usually written $p = kc$. In so far as the equation just derived is of the form of Henry's law, we may follow van't Hoff¹ who showed that "we may conclude that gases which on solution follow Henry's law, possess the same molecular weight in the solution as in the gaseous state, with only the possible exception that hydrate formation, always without change in size of the gaseous molecule, may occur."

The same result might have been arrived at in another way. In so far as a given substance A dissolves in B according to a linear relation between pressure and concentration, it follows Henry's law. In case this straight line coincides with the straight line drawn from zero to the vapor pressure of pure A, the solution is said to be ideal. Consequently the case of the ideal solution is a special case of Henry's law, which latter may be represented by a straight line of unpredictable slope, while the slope of the line for the ideal solution

¹ "Lectures on Theoretical Chemistry" 31 (1899).

has a very definite value. Consequently, since the ideal solution is a special case of Henry's law, and since any solution which follows Henry's law has its necessary characteristic that the molecular weight of the solute must be the same in the solution as in the vapor, this is to be added to the definition of the ideal solution.

We may therefore summarize our definition of an ideal solution as one whose formation is accompanied by no heat changes, and whose volume represents the sum of the volumes of its components before mixing—that is there are no volume changes. Furthermore, the partial pressure of each component is equal to its vapor pressure as a pure substance multiplied by its mol fraction in the solution and, lastly, the molecular weight of each component in the solution is the same as in the vapor above the solution. Then for the ideal solution according to Washburn,

$$p_1 = p_0 \frac{N}{N + n}$$

or

$$\frac{p_0}{p_1} = \frac{N + n}{N}$$

which is the form that will be used extensively later in the paper. Consequently we may write for the ideal solution Form I as:

$$PV_m = RT \ln \frac{N + n}{N}$$

and Form II as:

$$PV_1 = \frac{N}{n} RT \ln \frac{N + n}{N}$$

Also from $\frac{p_1}{p_0} = \frac{N}{N + n}$ we may get $1 - \frac{p_1}{p_0} = 1 - \frac{N}{N + n}$.

and consequently

$$\frac{p_0 - p_1}{p_0} = \frac{n}{N + n}$$

This is the form previously referred to as Raoult's law and is the relation Raoult claims to have arrived at empirically as a result of study of his brilliant vapor pressure measurements. It is therefore clear that the definitions by Washburn and by Lewis are equivalent and are capable of being derived from each other.

It would be well before proceeding further to point out that, although in the above development, we have shown that for a specific gas and a specific liquid, ideal solution properties permit the ideal solution equation to be converted into a form similar to Henry's law, these two relations are not equivalent. For definiteness these are here set down. Raoult's equation is

$$p_A = p_{0A} \frac{N_A}{N_A + N_B}$$

and Henry's law is expressed by $p = kc$.

The temptation is great to say the two forms are equivalent term for term but this is not true. The term p_0 is a perfectly definite, usually measurable, quantity, while the k of Henry's law is to be revealed only experimentally

far, Henry's law has been shown to be true only for dilute solutions. For such solutions there would be no change in its form if, instead of volume concentrations (grams per cc.), we substitute mass concentrations so that it might become:

$$p = k_1 \frac{N_A}{N_B}$$

where N_A and N_B represent mols of solute and solvent respectively. For the dilute solutions the difference is negligible between this form and

$$p = k_2 \frac{N_A}{N_A + N_B}$$

It is quite possible that this is the form in which Henry's law ought always to be expressed; but, so far, this has not been stated explicitly.¹ If we assume definitely that $k_2 = p_{0A}$, then we shall have idealized Henry's law into the expression of Raoult's law. In order to do this, however, it has been necessary to change the volume concentrations of Henry's law into the mass concentrations of Raoult's law. This change is not particularly significant in the dilute solutions to which Henry's law applies. It is important, however, that the specific constant of Henry's law must be replaced by the general constant of Raoult's law. It will be shown below that this cannot be done. Furthermore it is clear that for a gas above its critical temperature p_{0A} can have no physical significance.

Consider the case of a single gas dissolving in two or more different liquids under the same partial pressure of the gas above a fixed volume of liquid. The idealization of Henry's law into Raoult's law as indicated above, gives for the ideal solution

$$p = \frac{p_{0A}(M.V.)_B}{M_A} \frac{g_A}{V_B},$$

where g_A/V_B is the C of Henry's law, $(M.V.)_B$ the mol volume of liquid B and M_A the molecular weight of A. Then g_A ought to be inversely proportional to $(M.V.)_B$. In other words, if a gas in dissolving follows Henry's law, and if Henry's law is equivalent to the ideal solution equation of Raoult, then the solubility of the gas ought to be inversely proportional to the molecular volume of the absorbing liquid.

This may also be shown in the symbols previously used in this paper. For the ideal solution of the same gas in various liquids $p = p_0 \frac{n}{N + n}$. In the experiment the value of p , the partial pressure of the gas over the solution may be kept constant; p_0 will also be constant. Therefore $\frac{n_1}{N_1 + n_1} = \frac{n_2}{N_2 + n_2}$, where the subscripts refer to the two different solutions. This relation gives

$$\frac{n_1}{n_2} = \frac{N_1}{N_2}$$

¹ If Henry's law is to be expressed in mass concentrations, the distribution law must also be so expressed.

But since $N_1 = \frac{\text{volume of absorbing liquid (1)}}{\text{molecular volume of liquid (1)}}$ ghts
hat

and $N_2 = \frac{\text{volume of absorbing liquid (2)}}{\text{molecular volume of liquid (2)'}}$

if we use the same volume of absorbing liquid in each case, say 1 cc. the ratio of molecular solubilities of the gas in the two liquids is:

$$\frac{n_1}{n_2} = \frac{g_1}{g_2} = \frac{\text{mol volume of liquid (2)}}{\text{mol volume of liquid (1)}}$$

as was found before. It will be well to test this relation for some experimental cases.

Data for testing this relationship will be found in a study of the absorption of gases in petroleum by Gniewosz and Walfisz.¹ It is readily admitted that we have no knowledge of the molecular weight or volume of petroleum. But if we compare the absorption coefficients of the same gases in petroleum and in water, we need to take into account the molecular volume of neither. The ratio of the absorption coefficients ought to be a constant if the idealization of Henry's law is justified.

TABLE I
Absorption Coefficients at 20°

	(1) For Petroleum	(2) For Water	(1)/(2) Ratio
H ₂	0.0582	0.0193	3.02
N ₂	0.117	0.0140	8.36
O ₂	0.202	0.0284	7.11
N ₂ O	2.11	0.670	3.15
C ₂ H ₄	0.142	0.149	0.95
CO ₂	1.17	0.901	1.3
CO	0.123	0.0231	5.3
CH ₄	0.131	0.0350	3.7

It may be objected, however, that we cannot test this relation truly by reference to water because water is an abnormal liquid. For answer to that is brought the evidence collected by Woukoloff² who found the solubility of carbon dioxide in 1 cc. of carbon disulphide to be 0.844 cc., while 1 cc. of chloroform absorbs 2.758 cc. of carbon dioxide, the gas being in each case reduced to standard conditions and the absorption taking place in each case under a pressure of 478 mm. The molecular volume of carbon disulphide is about 80 cc. and of chloroform about 60 cc. but the absorption coefficients of 0.844 and 2.75 would hardly seem to be in inverse proportion to the molecular volumes.

¹ Z. physik. Chem., 1, 70 (1887).

² Compt. rend., 108, 674 (1889); 109, 61 (1889).

It seems evident, then, that Henry's law and Raoult's law are not equivalent. The constant in Henry's law may contain p_{0A} , $(M.V.)_B$, and M_A as has been shown above. In addition, however, it must contain some other factor whose nature is as yet unknown and which will represent the specific character of solubilities. Experimentally some liquids follow Raoult's empirical relation, while some gases in liquids follow Henry's law, also empirical. As yet no system is known which follows both simultaneously.

Considerable space has been given to this demonstration because some modern authors have treated these equations as equivalent, deriving Raoult's law from Henry's law. Frazer's derivation is a case in point.¹

"Since the pressure of a gas is proportional to the number of particles present per unit volume, the vapor pressure of a liquid due to any molecular species present, will be proportional to the number of particles of this molecular species present in the liquid

$$p = k \frac{N}{N + n}."$$

In other words, an ideal solution is postulated and put into the form of Henry's law using mass concentrations. The specific factor of Henry's law is then disregarded and k is set equal to p_0 . Naturally Raoult's law follows, since it was put in as the original assumption. One may well doubt also if association of the solvent has no effect and if the solute effect on displacement of the solvent equilibrium might not influence the relation, though it is explicitly stated that in an associated liquid like water the same relationship is true.

We can now come back to the relation $PV = RT$. Ever since van't Hoff showed that an analogy existed between the osmotic pressure of a solution and the gaseous pressure which would be exerted by the solute, and that both could be expressed as $PV = RT$, the V to be used has been the object of much speculation and the subject of considerable controversy. Probably the most commonly used value of V has been the volume of the solution containing one mol of solute. Van't Hoff made it quite definite that the solutions with which he proposed to deal were, "solutions so dilute as to be comparable with ideal or perfect gases, in which the action on one another of the dissolved molecules, as well as their actual volume compared with that of the space they inhabit, is so small as to be negligible." At best then, van't Hoff expected $PV = RT$ to have validity only for the very dilute solutions and he would not have been at all surprised that it failed for solutions of such concentrations as have been measured.

This approximation form has some value, however, if it be written $PV_1 = RT$. For such dilute solutions as those for which this is valid, we obtain from Form II

$$\frac{n}{N} = \ln \frac{p_0}{p_1}$$

¹ Taylor: "Treatise on Physical Chemistry," 1, 237 (1924).

which is a relation fundamental to the determination of molecular weights from freezing points or boiling points of solutions. The basic equation is that of Clausius-Clapeyron

$$\frac{d \ln p}{dT} = \frac{Q}{RT^2}$$

where Q is the latent heat of fusion or of vaporization of the pure solvent.

Substituting for $d \ln p$ its equal $\frac{n}{N}$, we have $\frac{n}{N} = \frac{QdT}{RT^2}$

But $n = g/M$, and for any given experiment with a fixed amount of a given solvent $\frac{QN}{RT^2}$ is a constant. Therefore $M = \frac{Kg}{dT}$ which is the usual equation used for the calculation of molecular weights, where K is the boiling point or freezing point constant. It follows then, that in so far as $PV_1 = RT$ is valid, $\frac{n}{N} = \ln \frac{p_0}{p_1}$ and molecular weights can be determined as shown above.

Both $PV_1 = RT$ and $PV = RT$ are justifiable approximations for dilute solutions. The former is in some cases the better form, yet $PV_1 = RT$ is always an approximation and will deviate from the facts more and more as the concentration of the solute increases. The extent of this deviation may be shown by reference to Form II as here derived,

$$PV_1 = RT \frac{N}{n} \ln \frac{p_0}{p_1},$$

or better yet by the form taken by this equation if we assume that we are dealing with an ideal solution. Form II then becomes Form IV

$$PV_1 = RT \frac{N}{n} \ln \frac{N+n}{N} \quad (IV)$$

since $\frac{p_0}{p_1} = \frac{N+n}{N}$. The case of the infinitely dilute solution may be considered, where n approaches zero.

$$\frac{N}{n} \ln \frac{N+n}{N} \text{ may be written } \frac{N}{n} \ln \left(1 + \frac{n}{N} \right)$$

On expansion, we obtain;

$$\ln \left(1 + \frac{n}{N} \right) = \frac{n}{N} - \frac{n^2}{2N^2} + \dots \text{ in powers of } n$$

Hence the expression becomes

$$\frac{N}{n} \left[\frac{n}{N} - \frac{n^2}{2N^2} + \dots \right]$$

which equals one as n approaches zero, and $\frac{n^2}{2N^2}$ and the succeeding terms of the expansion become negligible.

The evaluation of $\frac{N}{n} \ln \frac{N+n}{N}$ as n approaches zero is due to Professor

Virgil Snyder of the Cornell University Department of Mathematics. Since this term equals one as n becomes infinitely small, it follows that for the infinitely dilute solution $PV_I = RT$.

For any finite value of n , the osmotic pressure calculated from $PV_I = RT$ for an ideal solution will be too large since for finite values of n , $\frac{N}{n} \ln \frac{N+n}{N}$ will always be less than unity as shown in the development above when $\frac{n^2}{2N^2}$ and the succeeding terms of the expansion can no longer be neglected. So, for example, for the case when $N = 9n$ the value of $\frac{N}{n} \ln \frac{N+n}{N}$ will be 0.948 and when the solution is made up of two mols of solute to eight mols of solvent $\frac{N}{n} \ln \frac{N+n}{N}$ becomes 0.892. This all assumes an ideal solution and means that the osmotic pressure calculated from $PV_I = RT$ when the solute molecules constitute 10 percent of all the molecules present, will be about 5 percent larger than the osmotic pressure calculated from the real formula

$$PV_I = RT \frac{N}{n} \ln \frac{N+n}{N}$$

since for this concentration, actually $PV_I = 0.948 RT$. For aqueous solutions, some of which experimentally appear to behave something like ideal solutions, this means a concentration of about 6.2 molar which is more than the solubility of most solutes in water. Therefore we may say that below this concentration, in so far as a given solution is ideal, we can express its osmotic pressure by $PV_I = RT$ with less than five percent error.

The relation may be shown in another way. Suppose the data N , n , and V_I be shown for a given ideal solution. What will be the error involved in calculating the osmotic pressure from $PV_I = RT$? The actual osmotic pressure would be given by the full equation

$$PV_I = RT \frac{N}{n} \ln \frac{N+n}{N},$$

while the approximate value would be given by

$$P_A V_I = RT.$$

Dividing the first equation by the second we have:

$$\frac{P}{P_A} = \frac{N}{n} \ln \frac{N+n}{N}$$

or

$$P = P_A \frac{N}{n} \ln \frac{N+n}{N}$$

In other words, P_A as calculated from the approximate $PV_I = RT$ equation will always be larger than the actual P of the ideal solution since for any finite value of n , $\frac{N}{n} \ln \frac{N+n}{N}$ is always less than one. When $\frac{N}{n} = 9$ this value

is 0.948 and when $\frac{N}{n} = 4$ this value becomes 0.892. If necessary, we may drop the assumption of ideal solutions and more generally write

$$P = P_A \frac{N}{n} \ln \frac{p_0}{p_1}$$

which will probably have the same sort of value as in the ideal case.

This relation is interesting in view of the work of Swietoslawski¹ who discusses "Deviations from van't Hoff's Law." He treats $PV = RT$ as van't Hoff's law and tries to add correcting terms to this equation expressed as $P = nRT$ where n is the mols of solute in one cc. of solution. He gives Form I as here derived as having been derived thermodynamically as

$$P = \frac{RT}{V} \ln \frac{p_0}{p_1}$$

It will be seen that there is no molecular weight term, which should surely be included unless the R he has in mind be a specific gas constant R referring to one gram rather than one mol of gas. Also he defines V as the specific volume of the pure solvent which cannot be true. His suggestion to improve the applicability of $P = nRT$ is to change it to $P = xznRT$ where x is a measure of deviation of the solution from Raoult's law and z is a function of the relative molecular volumes of solute and solvent. It will be clear then, that, in so far as Swietoslawski used the volume of solution, he was not using van't Hoff's law for osmotic pressure and if he had used $PV_I = RT$ as here indicated, the difference between the osmotic pressure by this formula and by the accurate formula would not be influenced by the function z .

The z value of Swietoslawski does become a factor however if, as he does, $PV = RT$ is used, where V is the volume of solution. Form II is

$$PV_I = RT \frac{N}{n} \ln \frac{p_0}{p_1}.$$

If, in deriving Form II, we had pressed out not that volume (V_I) of solvent containing one mol of solute but a volume V of solvent equal to the volume of the solvent V_I , plus the volume of one mol of solute (MV_I), the expression for Form II would have been

$$PV = \left(\frac{N}{n} + \frac{(M.V.)_1}{(M.V.)_2} \right) RT \ln \frac{p_0}{p_1}, \quad (V)$$

which we shall denote by Form V. It is seen that this V is the volume of solution containing one mol of solute, and is equal to the volume of solvent containing one mol of solute plus the volume of one mol of solute. This added volume of solvent pressed out will equal the $\frac{(M.V.)_1}{(M.V.)_2}$ mols of solvent where

$(M.V.)_1$ is the mol volume of solute and $(M.V.)_2$ is the mol volume of solvent.

For dilute solutions $PV_I = RT$ is a justified approximation and for these same dilute solutions $PV = RT$ will differ little from it. From Form V, in so far as $PV = RT$ experimentally

¹ Bull., (4) 37, 263 (1925).

$$\left(\frac{N}{n} + \frac{(M.V.)_1}{(M.V.)_2} \right) \ln \frac{p_0}{p_1} = 1$$

or

$$\frac{n}{N + \frac{(M.V.)_1}{(M.V.)_2} n} = \ln \frac{p_0}{p_1}.$$

But for dilute solutions,

$$\ln \frac{p_0}{p_1} = \frac{p_0 - p_1}{p_0}$$

approximately. Therefore we have what appears to be a more accurate statement of Raoult's law derived from these equations,

$$\frac{n}{N + \frac{(M.V.)_1}{(M.V.)_2} n} = \frac{p_0 - p_1}{p_0}.$$

When the mol volume of the solute $(M.V.)_1$ is equal to the mol volume of the solvent $(M.V.)_2$, this expression is exactly that arrived at empirically by Raoult. In order to justify it, Raoult had to confine himself to dilute solutions experimentally just as has now been done in its derivation.

It will be seen at once that this expression involves a larger error than would have been introduced by assuming $PV_1 = RT$. In so far as this is true, we get from Form II

$$\frac{n}{N} = \ln \frac{p_0}{p_1} \quad (VI)$$

which is more accurate than the expression above including the mol volumes of the components.

Equation VI for dilute solutions gives

$$\frac{n}{N} = \frac{p_0 - p_1}{p_0}$$

which is the form Kendall¹ calls the "dilute-solution" equation, and he adds: "This relation is strictly valid only for solutions of infinite dilution, consti-

tuting the limiting case of the more exact equation: $\frac{n}{N} = \ln \frac{p_0}{p_1}$. The difference

between the calculated values for the two forms of the equation is, however, inappreciable even for a fairly concentrated solution."

It may be pointed out that $\frac{n}{N} = \ln \frac{p_0}{p_1}$ offers a method of finding the molecular weight of the solute in the solution or the solvent in the vapor. This method is perfectly valid only for the dilute ideal solution. In every other case $PV_1 = RT$ does not hold even approximately and should be replaced by $PV_1 = RT + f(Q)$ where Q is the heat of dilution and as yet the function is unknown. In so far as $f(Q)$ does not equal zero, as it does in the ideal solution, $\frac{n}{N} = \ln \frac{p_0}{p_1}$ will not serve for molecular weight determinations except by consideration of its effect.

¹ J. Am. Chem. Soc., **43**, 1391 (1921).

In spite of the fact that osmotic pressures for a solution as calculated from $PV_I = RT$ differ from the accurate value by a factor that contains no volume term and is not affected by the relative mol volumes of the solute and solvent, the accurate value of osmotic pressure does depend on the molecular volume of the solvent. Consider two ideal solutions of the same substance in different solvents A and B, the concentrations being such that $\frac{N}{n}$ is the same for both solutions. Then the values of $\ln \frac{N+n}{N}$ will be the same in the two solutions and the osmotic pressures of the two solutions will be represented by

$$P_A V_{MA} = RT \ln \frac{N+n}{N}$$

$$P_B V_{MB} = RT \ln \frac{N+n}{N}$$

where P_A and P_B are the osmotic pressures of the two solutions and V_{MA} and V_{MB} are the mol volumes of solvents A and B respectively.

Dividing, we get

$$P_A V_{MA} = P_B V_{MB}$$

In other words, the osmotic pressures of two ideal solutions at the same temperature and having the same value of $\frac{N}{n}$ are inversely proportional to the mol volumes of the solvents employed. This is just as valid for two non-ideal solutions for which the values of $\ln \frac{p_0}{p_1}$ are the same.

Of those who have attacked the van't Hoff equation for osmotic pressure, probably none has been more influential than G. N. Lewis.¹ In reviewing the situation, he discusses the inadequacy of the van't Hoff equation which to him has always meant $PV = RT$ where V is the volume of the solution containing one mol of the solute. Quite naturally it is easy to show that this equation does not represent the experimental facts over any large concentration range. Morse and Frazer² had improved the situation very appreciably by changing the volume of the solution empirically to mean the volume of the solvent water at its maximum density. This gave rather good agreement on their sugar solutions up to molar concentrations since that volume of solution differed but little from V_1 , which should have been introduced as here defined. No intimation is given that van't Hoff did derive perfectly accurate and general equations for the osmotic pressure. Instead, since $PV = RT$ as usually defined is of so little value and since even the modification of Morse and Frazer leaves much to be desired, Lewis proposes to discard the so-called van't Hoff equation $PV = RT$ and substitute for it in the study of solutions, Raoult's empirical law $\frac{p_0 - p_1}{p_0} = \frac{n}{N+n}$ which, although it has as yet no theoretical explanation does fit the facts remarkably well for a number of solutions.

¹ J. Am. Chem. Soc., **30**, 668 (1908).

² Am. Chem. J., **34**, 1 (1905).

Lewis then proceeds thermodynamically to derive an expression,

$$P - \frac{\alpha P^2}{2} = \frac{RT}{V_0} \ln \frac{p_0}{p_1} \quad (\text{III})$$

where " α is the coefficient of compressibility of the solvent, V_0 is its molecular volume," and the other terms are as we have previously defined them. This compressibility term will be shown later to be foreign to the discussion. If it is negligible and if V_0 be equivalent to V_M as defined in this paper, then Lewis' equation is the same as Form I. Lewis then proceeds to define the

perfect solution as one which obeys Raoult's law, $p_1 = p_0 \frac{N}{N+n}$. The thermodynamic equation then becomes, for the ideal solution

$$P - \frac{\alpha P^2}{2} = \frac{RT}{V_0} \ln \frac{N+n}{N} \quad (\text{VII})$$

Using this last equation, the calculated osmotic pressures for the sugar solutions of Morse and Frazer agree much better with the observed values than do the values calculated by the old $PV = RT$. It is observed that Lewis' new values are, in eight cases out of ten, farther from the observed values than are those calculated by Morse and Frazer. These solutions however, are normal or less, so the ideal equation is next applied to some solutions which Zawidski¹ has shown from vapor pressure measurements are ideal over the whole range. Lewis' Table V is here presented as Table II:

TABLE II
 $\text{C}_2\text{H}_4\text{Cl}_2$ in C_6H_6 at 50°

n	p_1	P van't Hoff	P Morse and Frazer	P Lewis	P Found
0.0	268.0	—	—	—	—
0.293	268.0	91	120	101	100
0.416	156.0	128	205	157	158
0.522	127.8	160	315	215	217
0.657	92.4	196	549	313	310
0.754	65.9	223	880	413	406
0.920	21.8	268	3290	743	735

In Table II the first column gives the mol fraction of solute; the second, the partial vapor pressure of the solvent, taken from Zawidski; the third, the osmotic pressure calculated by the van't Hoff equation; the fourth, that calculated by the equation of Morse and Frazer; the fifth, that calculated by equation (VII) (the equation above), while the last column gives the actual osmotic pressure obtained thermodynamically from the vapor pressures by means of equation (III), (the general equation above). Lewis concluded, "We see from these Tables how closely in these two cases the actual osmotic

¹ Z. physik Chem., 35, 129 (1900).

pressures agree with those calculated by equation (VII) and how far from the truth are the pressures calculated both by the van't Hoff equation and by that of Morse and Frazer."

Several interesting observations may be made concerning the Table. Of the compressibility term, Lewis says, "The second term in equation (VII) or (III) except at the very highest concentrations, is comparatively insignificant, amounting usually to only a few per cent of the value of P even when the osmotic pressure is as high as a thousand atmospheres." For the ideal solution V_0 is equal to V_M as here defined. Consequently the two equations given are practically the ones that van't Hoff gave and the same as Form I here derived. Therefore the osmotic pressures set down in the last column can be accepted as correct. The failure of those calculated by Lewis to agree with these will, by reference to equations (VII) and (III), be seen to be due

entirely to the fact that $\ln \frac{p_0}{p_1}$ does not exactly equal $\ln \frac{N+n}{N}$. In other words,

the solution of ethylene chloride in benzene is not quite an ideal solution and these equations afford a rather round-about way to demonstrate that. No advance is made over the van't Hoff or thermodynamic formula for the accurate calculation of osmotic pressures of concentrated solutions.

In the second place, it is quite evident that the equation $PV = RT$ where V is the volume of solution cannot express the facts and there is no good reason why it should be valid beyond the infinitely dilute solutions.

Finally, it may be observed that the values calculated by Morse and Frazer's method are increasingly higher than the actual osmotic pressures. For the ideal solution under discussion the volume of pure solvent is exactly equal to V_1 as here defined. Therefore, for the ideal case, the equation of Morse and Frazer is $PV_1 = RT$. It has already been shown why this equation yields values of P that are increasingly higher than the actual values; as the

value of $\frac{N}{n} \ln \frac{N+n}{N}$ the neglected term, gets smaller with increase in concentration, and if this be neglected the calculated value of P becomes increasingly larger.

The above discussion will also throw light on another objection made to what Lewis calls the van't Hoff equation. Hildebrand¹ recently expressed this objection on the ground that "it leads to absurd figures, for, as the proportion of solvent in the solution approaches zero, the osmotic pressure actually approaches infinity, while according to the equation of van't Hoff it should never exceed a few hundred atmospheres." Hildebrand is making the common mistake of substituting V the volume of the solution in which one gram molecular weight of the solute is dissolved for what we have called V_1 , the volume of the solvent in which one gram molecular weight of the solute is dissolved. The two are identical for infinitely dilute solutions, but not necessarily so for any other concentration. For the concentrated solutions

¹ "Solubility," 26 (1924).

V_1 becomes infinitely small and P therefore may go to infinitely large values. It should be clearly understood, however, that an equation of the form $PV = RT$ cannot accurately express osmotic pressures over any wide range of concentrations, no matter what definition be given the V . If V_1 be used instead of volume of solution, the range is increased and the error is readily calculable for the ideal solution.

There is however no limit to the applicability of Forms I and II as here derived except the assumptions introduced into their derivations. They are valid for solutions of any concentration, so long as the solvent vapor over the solution can be regarded as a perfect gas. This means that the real equations of van't Hoff do meet the second objection of Lewis and Hildebrand and do permit the calculation of infinite values of P for infinite concentration of the solution. In Form I, $\ln \frac{p_0}{p_1}$ approaches infinity for infinitely concentrated solutions and therefore P may have infinitely large values since $\frac{RT}{V_M}$ is practically a constant. The same result is obtained from Form IV,

$$PV_I = RT \frac{N}{n} \ln \frac{N+n}{N}. \quad (IV)$$

Calculation shows that as $\frac{N}{n}$ decreases (concentration increases), the value of V_I decreases much more rapidly than does $\frac{N}{n} \ln \frac{N+n}{N}$. Consequently P must increase very rapidly and approach infinity for infinitely small values of $\frac{N}{n}$ (infinite concentration).

Before leaving these observations on the formula the matter of compressibility ought to be discussed. In addition to Lewis, Porter, Berkeley, and others have added to our Form I a compressibility term $\pm \frac{\alpha P_2}{2}$ where α is the compressibility of the pure solvent. If Form I,

$$PV_\kappa = \frac{RT}{M_2} \ln \frac{p_0}{p_1}$$

expresses the relation, then no further term is required. But if the value of V_κ of the formula changes with osmotic pressure some correction will be required, for the observed osmotic pressure will be greater than it would be if V_κ were constant.

It is first offered that one could not hope to compress water by a piston permeable to water, and it is not readily apparent why the sugar makes any difference. In other words a variation of osmotic pressure because of solvent compressibility implies that when pressure is put on a sugar solution by means of a piston permeable to the water, the water is compressed.

To show this in another way, an analogy may be resorted to. If a mixture of nitrogen and hydrogen were separated from pure hydrogen by a wall permeable only to hydrogen, and if pressure were applied to the mixture,

hydrogen would pass through from the mixture to the pure hydrogen until its partial pressure in the mixture would be the same as in the pure hydrogen. This means that the hydrogen would not be compressed—its volume concentration remains constant in the mixture. The nitrogen however is compressed. It is suggested that this is analogous to the situation in a solution and that there only the solute is compressed by pressure applied through a piston permeable to the solvent.

The Evolution of the Ideal Solution Equation

The modern treatment of the theories of solutions owes much to the historic researches of F. M. Raoult who measured the freezing points and vapor pressures of a great many solutions in various solvents and from the results for dilute solutions expressed the relation between vapor pressure and concentration in the law that bears his name. This law is usually expressed

mathematically as $\frac{p_0 - p_1}{p_0} = \frac{n}{N + n}$ and is put in words by the statement that

the relative lowering of the vapor pressure of a pure solvent is equal to the mol fraction of the solute in the solution. The various papers of Raoult would indicate that he arrived at this law empirically as the one best expressing his experimental results for dilute solutions; but further study reveals that he was probably aided largely in deriving the generalization by the contemporaneous theoretical work of van't Hoff.

The earliest reported work of Raoult¹ on the vapor pressures of solutions had to do with the relation that was found to exist between the lowering of the freezing point, and the lowering of the vapor pressure at 100° C by the same aqueous solutions. The result of these experiments was that for concentrations of one gram of salt per 100 grams of water

$$7.6\Delta = p_0 - p_1$$

where Δ represented the freezing-point lowering and $p_0 - p_1$ the vapor pressure lowering due to the salt. The fact that this formula comes out so simply is a result of coincidence that the molecular lowering for solutions in water is nearly the same as the molecular weight of water. This will be elaborated further when the formula as finally reached is developed.

Another result of this paper was that solutions of salts in water were shown to contain too many disturbing factors for effective generalization so that for several years Raoult worked on solutions of various solutes in organic solvents or of organic solutes in water. The freezing points of many of the latter type of solutions were measured² and it was found that the molecular lowerings of the various organic solutes in water were practically identical and averaged about 18.5°.

In the same year,³ the freezing-point investigations were extended to various organic solvents and molecular lowerings were reported as follows: in water

¹ Compt. rend., **87**, 167 (1878).

² Compt. rend., **94**, 1517 (1882).

³ Compt. rend., **95**, 187 (1882).

37; formic acid 28; acetic acid 39; benzene 49; nitrobenzene 70.5; and ethylene bromide 117.

In each case, except that of water as solvent, if these lowerings produced by one mol of solute in 100 grams of solvent were divided by the formula weight of the solvent, the quotient came out approximately 0.62. Raoult generalized this to mean that a molecule of any compound dissolving in 100 molecules of any liquid lowers the freezing point about 0.62 degrees. The case of water was very perturbing for the quotient for water came out 2.05. This Raoult explained by suggesting that the "physical molecule must be

made up of two or three chemical ones" because $\frac{37}{54} = 0.685$ which was of the

order of 0.62. It should be added that in all the solvents listed above, Raoult found values of the molecular lowering that grouped themselves about two average values, the one being double the other. The molecular lowerings listed above are all the double values which Raoult believed to be normal while the others were abnormal. He was not exactly consistent in this for in a later paper¹ he discusses the value of the freezing-points for determining

the molecular weight of the solute and sets the equation as, $M = \frac{19}{A}$, when M is the molecular weight of the solute, A is the grams of solute per 100 grams of water and 19 is the molecular freezing-point lowering of water. In the next year, he reported freezing-point lowerings in thymol and naphthalene as solvents stating that the value 0.62 is also valid for them.

In a longer paper, published in 1884, Raoult¹ gives some slightly different numerical data, Table III.

TABLE III

Solvent	Mol. Wt. Solvent	Maximum molecular lowering, 1 mol per 100 g	Molecular lowering 1 mol per 100 mol
Water	18	47	2.61°
Formic Acid	46	29	0.63
Acetic Acid	60	39	0.65
Benzene	78	50	0.64
Nitrobenzene	123	73	0.59
Ethylene dibromide	188	119	0.63

Raoult points out that, with the exception of water, the molecular lowering varies only from 0.59° to 0.65° with a mean value of 0.63°. "Water is the only exception; but that is not surprising for a liquid which shows many other peculiarities and it is permissible to explain the anomaly by assuming that each of the physical molecules, of which it is formed, consists of several chemical molecules united together. At a time when I had only obtained a small

¹ Compt. rend., 101, 1056 (1885).

number of molecular lowerings higher than the mean lowering of 37 in aqueous solutions, I believed that the physical molecules of water were composed of three chemical ones. In fact, if we divide 37 by 18×3 , we get as quotient 0.685 which is not very far from the mean quotient of 0.63 obtained with the other solvents. I have called attention to this in an earlier paper.¹ But new determinations make it no longer possible to consider the molecular lowerings distinctly higher than 37 as doubtful. I am, therefore, compelled to recognize that molecular lowerings in water may really rise to 47, a maximum value in many cases where the dissolved substances do not decompose. To explain such a lowering, *it is sufficient to assume that the molecules of water are united in fours*, at least near zero. The quotient of 47 by 18×4 is 0.65, a number remarkably close to the mean value of 0.63 obtained with the other solvents."

The molecular lowering of 47 is obtained with potassium ferrocyanide, barium chloride, potassium oxalate, etc. It is quite evident that Raoult had not decided which were the normal lowerings and that he believed that the molecular weight of the solvent as liquid was a factor. Some people still think so. It is also interesting to note that at this time he considered acetic acid as normal as benzene. Of course the real difficulty is that the value of 0.63 has no theoretical significance. It is purely a coincidence that acetic acid gives 0.65, postulating a molecular weight of 60.

There were a few more papers confirming and extending the work on cryoscopy but it was gradually neglected and the measurements of vapor pressures resumed. On Dec. 6, 1886 it was reported² that "if one dissolves one molecular weight of any compound in 100 gms. of ether, the vapor pressure of the liquid is diminished by a constant fraction of its normal value; this fraction is about 0.71 at all temperatures between 0° and 25°." This was formulated mathematically into

$$\frac{p_0 - p_1}{p_0} \times \frac{M_1}{P} = K$$

where M_1 is the molecular weight of the solute, P is the number of grams of solute in 100 grams of ether and K is practically a constant varying between 0.67 and 0.74 with 0.71 as its mean value. On April 4, 1887, it was reported³ that up to 7 mols of solute per 100 grams of ether, the lowering of the vapor pressure can be expressed by the formula

$$\frac{p_0 - p_1}{p_0} \frac{M}{P \times 74} = D$$

where 74 is the molecular weight of ether and D is a constant whose value is approximately 0.0096. Further study of other solvents led to the statement⁴ read on May 23, 1887 to the effect that "one mol of solute, not a salt, dis-

¹ Compt. rend., 95, 1030 (1882).

² Compt. rend., 103, 1125 (1886).

³ Compt. rend., 104, 976 (1887).

⁴ Compt. rend., 104, 1430 (1887).

solving in 100 mols of any solvent lowers the vapor pressure of the liquid by a fraction nearly constant and about 0.0105." This is equivalent to replacing the 74 in the equation above by the molecular weight of the solvent under discussion, and is the nearest Raoult had come to the earlier formula usually attributed to him. Raoult never found D of the above formula to be 0.0100 but gave values that varied in different solvents between 0.0096 and 0.0105. If however we may assume 0.0100 to be a fair average, we may write the above

equation as

$$\frac{p_0 - p_1}{p_0} = \frac{P}{M_1} \frac{M_2}{100}$$

where $p/M_1 = n$, the mols of solute present and $100/M = N$, the mols of solvent present. This equation then becomes

$$\frac{p_0 - p_1}{p_0} = \frac{n}{N}$$

which Ostwald gave as the earlier form of Raoult's equation, and which had to be given up because of the absurdity it led to when $n = N$ and p_1 had to become equal to zero.

In all this work there had been no reference to van't Hoff whose important paper relative to the vapor pressure of solutions was presented October 14, 1885 before the Swedish Academy and published¹ early in 1886. Van't Hoff had concerned himself greatly with Raoult's work and had calculated Raoult's molecular lowering of the freezing points from the temperature and heat of fusion of the pure solvent arriving at values that on the whole agreed very well with those observed by Raoult. This was taken by van't Hoff as an additional proof that the analogy between osmotic pressure and gaseous pressure was justified.

This work of van't Hoff must have come promptly to Raoult's attention and his next paper,² November 7, 1887 is devoted to a consideration of van't Hoff's work. Raoult points out that van't Hoff has shown on theoretical grounds that "i," the famous van't Hoff correction term, must be calculable from

$$i = 101 \frac{M_1}{M_2} \frac{p_0 - p_1}{p_0}$$

where $\frac{p_0 - p_1}{p_0}$ is the relative lowering of the vapor pressure by one gram of solute in 100 grams of solvent. Since "i" equals unity for most of the cases

with which Raoult has dealt we may write, as he did, $\frac{1}{101} = \frac{M_1}{M_2} \frac{p_0 - p_1}{p_0}$

But the left hand side of this equation is $\frac{g_1}{g_1 + g_2}$ where g_1 and g_2 represent grams

of solute and solvent respectively and in this particular case is equal to 0.0099 which Raoult said was not far from his 0.0105 value experimentally obtained.

¹ Kongl. svenska Vetenskaps Akademiens Handlingar, 21, 3 (1885).

² Compt. rend., 105, 857 (1887).

More light may be shed on this relation by considering that since $\frac{p_0 - p_1}{p_0}$ is the relative lowering in vapor pressure produced by one gram of solute in 100 grams of solvent, $\frac{M_1}{M_2} \frac{p_0 - p_1}{p_0}$ will be the lowering produced by one mol of solute in 100 mols of solvent and this is shown by van't Hoff to be equal to $1/101$. In other words, the complete so-called Raoult law,

$$\frac{n}{N + n} = \frac{p_0 - p_1}{p_0}$$

was in the theoretical derivation of van't Hoff.

It is emphasized that up to the time at which Raoult comments definitely on van't Hoff's work, he had never even stated explicitly the relation $\frac{n}{N} = \frac{p_0 - p_1}{p_0}$, although it was implied in the early paper of 1887. The following year he makes this explicit for some solutions in alcohol which were expressed by $C' = \frac{p_0 - p_1}{p_0 n}$ where C' is the molecular lowering due to one mol of solute in 100 mols of alcohol and varied from 0.0091 to 0.0110 with a mean value of about 0.0104.

In the same year,¹ however, he did adopt the new form from van't Hoff; but, for most solutions, his data had to be expressed by $\frac{p_0 - p_1}{p_0} = K \frac{n}{N + n}$ where K was a constant varying from 0.70 to 0.90 for solutions of moderate concentrations. For dilute solutions the law had a special expression in that $K = 1$ for dilute solutions. So that, not until a year after Raoult had commented on van't Hoff's theoretical deduction of it, did he arrive at the equation which still bears his name.

Now that we have this statement of the law it would be well to retrace our steps for then we discover that the statement in the first paper here discussed, $7.6\Delta = p_0 - p_1$ is the result of a coincidence and is not fundamental. The later papers on freezing points in aqueous solutions showed that $\Delta = 18.5 \frac{g_1}{M_1}$ where Δ is the depression of freezing point, 18.5 the depression due to one mol of solute in 100 grams of water, g_1 , the weight of solute in 100 grams of water and M_1 its molecular weight. For dilute solutions $\frac{n}{N} = \frac{g_1 M_2}{g_2 M_1} = \frac{p_0 - p_1}{p_0}$ where $g_2/M_2 =$ mols of solvent present. In these experiments $g_2 = 100$ so that $\frac{g_1}{M_1} = \frac{100}{M_2} \frac{p_0 - p_1}{p_0}$. Substituting in the above equation

¹ Z. physik. Chem., 2, 353 (1888).

$$\Delta = 18.5 \frac{100}{M_2} \frac{p_0 - p_1}{p_0}.$$

But for water, $M_2 = 18$ and $p_0 = 760$ at 100° . Therefore, since 18 is so nearly 18.5, the experimental value, we have $7.6 \Delta = \frac{p_0 - p_1}{p_0}$

which is purely accidental. For benzene as solute we should have had

$$7.6 \Delta = \frac{50}{78} (p_0 - p_1)$$

Since it has been shown earlier that $\frac{p_0 - p_1}{p_0}$ is only an approximation for $\ln p_0/p_1$ we may write the true equation for the freezing-point lowering as

$$\Delta = \frac{100 K}{M_2} \ln \frac{p_0}{p_1}$$

At the freezing-point, this will hold for all substances. Since there is no term for the molecular weight of the solute, the relation is true for all solutes, sugar, potassium chloride, sodium sulphate, regardless of dissociation, which is what Raoult found. But it is only when there is no heat of dilution that we are justified in comparing freezing-point lowerings with vapor pressure lowerings at the boiling temperature of the pure liquid.

Before leaving the discussion of Raoult's work, we ought to emphasize that in all of it Raoult considered only the molecular weight of the solvent in the solution. This brought him to grief in the study of solutions in acetic acid.¹ It was found that for twelve different solvents the vapor pressure

lowerings were expressed by $\frac{p_0 - p_1}{p_0} = k \frac{n}{N}$ where k was practically one. But

the same eight solutes in acetic acid gave values of k that averaged 1.61 when the molecular weight of acetic acid was taken as 60, its formula weight

As Raoult says, using 60 in the formula is equivalent to assuming that the physical molecule of boiling, liquid, acetic acid contains only a single chemical molecule, $\text{CH}_3\text{CO}_2\text{H}$. "We must seek the cause of this exceptional discrepancy in the considerable error that we make without doubt in taking for the *physical* molecular weight M_1 of liquid acetic acid the value 60 which represents its *chemical* molecular weight. In all probability, *at a given temperature, the constitution of the physical molecule of a substance is the same in the liquid state as in the saturated vapor.*"² If this is really so, the physical molecular weight of boiling, liquid, acetic acid must be equal to $60 \times 3.35/2.08$ or 97."

In a longer paper, published the same year, Raoult³ says much the same thing at greater length. "When dissolved in benzene, nitrobenzene, or ethy-

¹ Raoult and Recoura: *Compt. rend.*, **110**, 402 (1890).

² [This is not true for water.]

³ *Ann. Chim. Phys.*, (6) **20**, 353 (1890).

lene dibromide, the molecules of acetic acid are formed of two chemical molecules, since the molecular weight of this acid in these solutions is 120 as shown by cryoscopic measurements.

"In the vapor state the same tendency to condensation shows itself. The density of the saturated vapor of acetic acid is much higher than its normal density. This latter is, in fact, 2.08, while the vapor density under atmospheric pressure is, according to M. Cahours, 2.90 at 140°, 3.12 at 130°, and 3.20 at 125°, which, by extrapolation, gives 3.35 for the density of the saturated vapor of acetic acid at the boiling-point, 118°. The mean molecular weight of acetic acid in its saturated vapor is, therefore, at this temperature, $60 \times 3.35/2.08$ or 97, as if this vapor were formed of a mixture of 38 simple molecules and of 62 double molecules.

"If the molecules of the saturated vapor are twinned to some extent, it is probable that those of the liquid formed by their condensation are also twinned, and it is reasonable to assume that the degree of polymerization is the same. According to this hypothesis, the mean molecular weight of M' of liquid acetic acid at the boiling-point, 118°, is 97 just as it is for the saturated vapor.

"If in equation 8 $\left[\frac{f - f'}{f' P} \times \frac{M}{M'} = k \right]$ we make $M' = 97$ instead of $M' = 60$, we find $k = (1.61 \times 60) / 97 = 0.997$, just as it should be according to the general law expressed in equation 5

$$\left[\frac{f - f'}{f} \cdot \frac{n + n'}{n} = 1 \right].$$

"This is an important argument in favor of the hypothesis of the identity of molecular constitution of liquids and their saturated vapors at the same temperature, and also in favor of the comprehensiveness of the law announced above, with the limitation that this law applies to the physical molecules as they actually exist in the solution."

When the paper of February 24 was translated into German,¹ van't Hoff appended a note to the translation, explaining that the molecular weight of the solvent in the vapor ought to be introduced. It is not stated either by Raoult or by van't Hoff that van't Hoff had called Raoult's attention to this fact before the first Raoult and Recoura paper appeared; but the paper was presented to the French Academy on February 24 and was published in German on May 23. There is no obvious reason why Raoult should have bothered his head about vapor densities unless it had been suggested to him by van't Hoff. Whether the suggestion came from van't Hoff or not, it was apparently misunderstood by Raoult to mean that the molecular complexity of acetic acid was the same in the liquid and in the vapor. Van't Hoff was quite clear that this is not necessarily so, because he ends his note with the words that "it does not follow from this agreement that liquid acetic acid also shows this abnormal molecular weight."

¹ Raoult and Recoura: *Z. physik. Chem.*, 5, 426 (1890).

It apparently did not occur to Raoult that his conclusion as to the equality of molecular weights in liquid and vapor contradicted his earlier work necessitating the assumption of 36 or 54 for the molecular weight of liquid water, because the vapor density corresponds fairly closely to a molecular weight of 18. It is also interesting to note that Raoult did not even refer to the discrepancy between his present conclusion about acetic acid and his previous one, based on freezing-point lowerings, that acetic acid is just as normal as benzene.

It is clear that in the equation $(p - p')/p = n/(N + n)$, the molecular weight to which N refers is the molecular weight in the vapor. In the case of ideal solutions, the molecular weight is the same in liquid and in vapor; but it is misleading to ignore the theoretical significance of the term.

The conclusions to be drawn from this section are as follows:

1. It has been shown that up to the time when van't Hoff first presented his theoretical treatment of solutions, Raoult had not yet proposed explicitly

$\frac{p_0 - p_1}{p_0} = \frac{n}{N}$ to express the relation between concentration and vapor pressure of a solution.

2. In van't Hoff's equation $i = 101 \frac{M_1}{M_2} \frac{p_0 - p_1}{p_0}$ there is the explicit statement of the ideal solution equation since for such solutions $i = 1$, and $\frac{M_1}{M_2} \frac{p_0 - p_1}{p_0}$ represents the relative lowering of the vapor pressure in a solution containing one mol of solute to 100 mols of solvent. We then have $\frac{n}{N + n} =$

$\frac{p_0 - p_1}{p_0}$ the ideal solution equation which bears Raoult's name.

3. Raoult never accepted this as valid except for very dilute solutions. For all other solutions he continued to add a specific constant.

4. In spite of van't Hoff's demonstration to the contrary, Raoult continued to deal with the molecular weight of the solvent in the solution and not in the vapor. Even in 1890 Raoult did not understand the physical significance of the terms in the equation which bears his name.

The Determination of Volumes in Solution

The form of the osmotic pressure-vapor pressure equation here derived affords a new method of attack on an old problem that has drawn the attention of many workers. This problem is to determine the volume in the solution of the components of the solution. The process of solution is usually accompanied by some volume change so that the volume of the resulting solution is greater than, or less than, the sum of the volumes of the components before they were mixed. Only in the ideal solution as here defined will the volume of each component be the same after mixing as before. In every other case we must conclude that one or both components have expanded or contracted in the process of solution. The problem becomes of especial interest for a few

solutions which behave similarly to sodium hydroxide. "When four grams of sodium hydroxide are dissolved in ninety-six grams of water at 0° , the total volume is 0.6 cc. less than that of the original water."¹

It is rather improbable that the sodium hydroxide could have a negative volume of 0.6 cc. so that the determination of the specific volumes of the water and the sodium hydroxide becomes an interesting problem. This specific problem will not be solved here; but general methods for its attack will be outlined, and, in particular, a new one involving the use of Form I.

Cameron and Robinson² have given a good historical summary of the methods that have been used to solve this problem; but their assumption that all the volume change observed was due to the water seems somewhat improbable, and their condensation factors do not appear especially significant.

Among the earlier contributions to this problem was that of Gouy and Chaperon³ who, in studying the effects of gravity on change in concentration,

incidentally gave $K \frac{dw}{D_0}$ as the volume increase when dw grams of pure solvent of density D_0 was added to unit volume of solution, K being a contraction or expansion coefficient characteristics of the solution. Since this coefficient must depend on concentration, it will be represented by X to show it is a variable. Gouy and Chaperon obtained as a value:

$$X = \frac{D_0}{D} \left(1 - \frac{dD}{dw} \right),$$

when D is the density of the solution. The volume of dw grams of solvent in the solution is $X \frac{dw}{D_0}$ and if dw equals one, the volume increase is V_x as defined in Form I. Consequently,

$$V_x = \frac{1}{D} \left(1 - \frac{dD}{dw} \right).$$

Mr. Danforth Hale of this department has made a much simpler derivation of the same relation. We have:

$$D = \frac{M}{V}$$

in which D , M , and V , are the density, mass and volume of any solution. But M may be considered as made up of, the mass (m) of the solute which may remain constant, and the mass (w) of the solvent which is varied. Then

$$VD = m + w$$

differentiating

$$VdD + DdV = dw$$

and

$$\frac{dV}{dw} = \frac{1}{D} \left(1 - V \frac{dD}{dw} \right) = V_x$$

¹ Bousfield: *Trans. Faraday Soc.*, **13**, 141 (1917).

² *J. Phys. Chem.*, **14**, 1, 569 (1914).

³ *Ann. Chim. Phys.*, (6) **12**, 384 (1887).

This is seen to be equivalent to the expression of Gouy and Chaperon since they considered unit volume.

Teed¹ has calculated the value of the volume change coefficient by considering as simultaneous equations:

$$A a + B b = 100$$

$$A' a + B' b = 100$$

in which A and B are two original volumes of pure components which on mixing give one hundred volumes of solution, A' and B' are two slightly differing volumes also giving one hundred volumes of solution; and a and b are volume-change coefficients which are assumed to be constant over the narrow concentration range in question.

Unfortunately, the method is not correct, because a and b are not constants. If one takes the extreme case where $a = 1$ and solves for the volume change coefficient, one is really assuming that b is constant. For the present, all one can do is to attribute the whole change of volume to A and then to B , thus getting two volumes between which the true volume probably lies.

It has been suggested by Bancroft that the whole question of the determination of volumes of the components in a solution may be solved by the use of Form I to solve for V_k in those solutions for which the data are available. The usual plan has been to calculate V_k by various methods and then to calculate the osmotic pressure. This was the method of Berkeley, Hartley, and Burton² who applied a simplification of Porter's expression to the data for some sugar solutions. Their form was

$$P\bar{s} = RT \ln \frac{p_0}{p_1}$$

in which \bar{s} is our own V_k and was calculated from considerations similar to those just advanced for the volume change on solution together with reference to the compressibilities. Neither in Porter's own paper nor in Berkeley's does the molecular weight of the solvent vapor appear. The reason for this is not known; but this molecular weight must be introduced if one calculates the osmotic pressures as calculated by Berkeley. In Table IV the four more concentrated solutions are calculated from Berkeley; data for the two more dilute solutions coming from a different source as described below.

TABLE IV

C	$\ln \frac{p_0}{p_1}$	\bar{s}	P calc.	P obs.	V_k calc.	Sugar Density

¹ "Volume Change on and in Solution" (1926).

² Phil. Trans., 218A, 295 (1919).

In Table IV, the first column shows the concentration of the solutions in grams of sucrose per 100 grams of water; the second column gives the natural logarithm of the ratio of the vapor pressure of pure water to the vapor pressure of the solution. In the third column are shown the values of \bar{s} (our own V_g) calculated by Berkeley from compressibility data and from considerations analogous to those advanced by Bancroft. These values of s and $\ln \frac{p_0}{p_1}$ when substituted in his equation

$$P_s = RT \ln \frac{p_0}{p_1}$$

gave him his osmotic pressures in atmospheres shown in column four which are found to be quite close to the actual osmotic pressure observed for those solutions shown in the fifth column.

The method of Bancroft is exactly the opposite to that of Berkeley. The new method consists in substituting the values observed for P and $\ln \frac{p_0}{p_1}$ and from them, calculating V_g by means of the equation

$$V_g = \frac{RT}{PM_2} \ln \frac{p_0}{p_1},$$

which is Form I as here derived and in which V_g is the volume of one gram of the solvent *in the solution*. The sixth column shows the values of V_g that have been so calculated and it is emphasized that these values are as exact as the osmotic pressures and vapor pressures which were very carefully measured.

It will be observed from the Table that the values of V_g thus calculated differ from the s values of Berkeley by less than 0.3%. This agreement may be interpreted to mean that the various refinements introduced into Berkeley's calculations were nearly correct, and achieved practically the same result as this new, more direct, and accurate method. Berkeley also gives data

on $\ln \frac{p_0}{p_1}$ and \bar{s} for three other solutions whose concentrations are all greater than 179 grams of sugar per 100 grams of water. Since this is the value usually given for the solubility of sucrose in water at 0°C., one wonders how these values were observed. No osmotic pressures are given for these last solutions.

Before describing the source of the data for the first two solutions in Table IV, the meaning of the last column may be explained. If we know the densities of the sugar solutions, we can calculate the volume of a definite weight of the solution. Then, if by such calculations as have just been given for V_g , we can determine the volume in the solution of one gram of water, multiplying this by the weight of water in the solution gives the volume occupied by the water. Subtraction of this volume from the volume of the solution gives the volume occupied by the sugar in the solution. Knowing the weight of the sugar and its apparent volume, we can calculate the apparent density of the sugar in the solution. These values as calculated for the solutions in ques-

tions are shown in the last column of Table IV. If, as is commonly held, in the process of solution, a solid undergoes a volume change comparable with its volume change on fusion, we should expect the densities of sugar in solution to be less than 1.588, its density as a solid. With this view, the data of the first two solutions are in better qualitative agreement. Also they agree better with the calculations of Teed. It is observed in both sets that the apparent density of the sugar decreases with increase in concentration. Much more work may well be spent on this point. In this calculation the tacit assumption has been made that each gram. of water occupies the same volume as every other gram of water.

In addition to the data from Berkeley, two other calculations were made for more dilute solutions. The results of these calculations are shown in the first two lines of Table IV. The osmotic pressures were taken from the measurements by Morse and the vapor pressures of sugar solutions of as nearly as possible the same concentrations were given by Dieterici.

Morse gives the osmotic pressure of a solution containing 20.52 grams of sucrose per 100 grams of water as 14.381 atmospheres. Dieterici reports the lowering of the vapor pressures of a solution of 20.66 grams sucrose per 100 grams of water as 0.052 mm. of mercury. Then $p_0 = 4.569$ and $p_1 = 4.517$

and $V_g = \frac{RT}{PM_2} \cdot \ln \frac{p_0}{p_1}$ then becomes:

$$V_g = \frac{0.08207 \times 273}{14.381 \times 0.018016} \ln \frac{4.569}{4.517}$$

from which $V_g = 0.9893$ cc.

Again, Morse gives as the osmotic pressure of a solution containing 34.20 grams sucrose per 100 grams of water 24.825 atmospheres and Dieterici gives the lowering of the vapor pressure by a solution containing 34.25 grams sucrose per 100 grams of water as 0.089 mm. of mercury. From these data $V_g = 0.9840$. These last two sets of data are those shown first in Table IV.

Table IV shows that these values of V_g are self-consistent but that they do not agree with those calculated from Berkeley's data. In both cases, with rising sugar concentration, the value of V_g decreases. The two sets of synthesized data are for more dilute solutions than those of Berkeley's solution containing 56.5 grams of sugar per 100 grams of water and they presumably should be greater.

It may be added that the values of V_g for the two more dilute solutions fall practically on the curve plotted from the densities of sugar solutions while those calculated from the data of Berkeley are decidedly different. In Berkeley's table summarizing the experiments, \bar{s} for the solution containing 81.2 grams of sugar is given as 0.99157, but in the Table first recording the values of \bar{s} as calculated from the density and compressibility data, the value is given as 0.98157. This however would have no effect on the present calculation of V_g . In a note at the end of the paper is given a corrected value for $\ln (p_0/p_1)$ for this solution as 0.5239. This is a rather large correction and makes the calculated V_g become 0.9685 which is apparently much too low.

It has been found that except for this solution the values of V_x calculated by the method of Bancroft agree within 0.2% except for this concentration in question. The conclusion is drawn that either some abnormal effect enters at about that concentration, absent above or below it, or that the osmotic pressure for that concentration is less accurate than the rest.

Application of van der Waals' Formula to Osmotic Pressures

Soon after van't Hoff derived the relationship between osmotic pressure and the gas pressure of the solute, it became evident that the convenient approximation $PV = RT$ suggested by van't Hoff could not express the facts of osmotic pressure for solutions of finite concentrations any more than $PV = RT$ expresses the relation for a gas over the whole range. As indicated above, van't Hoff knew that this would be true and early stated that these deviations appeared in the two cases for the same reason.

Naturally, the first method of attack was to test the applicability of van der Waals' equation which was known to express the behavior of gases. Numerous workers have made efforts to express osmotic pressures by equations having a form similar to van der Waals' equation $(P + \frac{a}{V^2})(V - b) = RT$

in which, for gases, V is the volume occupied by the gas, $\frac{a}{V^2}$ is a term correcting for the mutual attraction of the gas molecules and b is a term correcting for the volume occupied by the gas molecules themselves. In the applications of this type of formula to actual data, it has been found that the data for osmotic pressures may be represented fairly well by $P(V - b) = RT$. One of the earliest of these applications was made by A. A. Noyes¹ who calculated osmotic pressures from the freezing-points of Beckmann. These osmotic pressures were then found to fit rather closely into a complicated formula which might be simplified into $P(V - d) = K$. Seven years later Noyes and Abbot² reported work done on some ethereal solutions of which they measured the vapor pressures. By means of a formula newly developed, which simplifies into our Form I, they calculated the osmotic pressures of these solutions, and found that $PV = RT$, where V equals volume of solution, fitted quite well over the range covered, 0.0 – 0.25 mols of nitrobenzene or naphthalene per liter.

Sackur³ also used freezing points to calculate osmotic pressure and found that $P(V - b) = RT$ was quite satisfactory. Although he was using the data of Morse and Frazer, he chose to represent by V the volume of solution, showing that thus the calculations came out better than by the use of volume of solvent which they had used. The difference between $V - b$ and V_1 will probably be rather small for the dilute solutions, so the advantage is not marked.

¹ Z. physik. Chem., **5**, 53 (1890).

² Z. physik. Chem., **23**, 56 (1897).

³ Z. physik. Chem., **70**, 477 (1910).

Bousfield also used the data of Morse and Frazer to support his hydration theories. He derives the formula,

$$P(h - n) = R'T$$

where $h - n$ represents the amount of free water and R' is not the gas constant. By this use of such an equation he calculated that at $20^{\circ}\text{C}.$, N , the hydration factor for sucrose comes out 6, and this factor diminishes with increase in temperature. Before leaving this matter, it might be well to point out that Frazer and Myrick¹ themselves were able to represent their own measurements of osmotic pressure by our Form I, up to 6.5 molar concentration and osmotic pressure of over 250 atmospheres.

It is, therefore, clear that the method offered in this section is not particularly new, but is decidedly more extensive than those previously published. If we assume that the solution studied is an ideal solution, we may then by,

$$PV_M = RT \ln \frac{N + n}{N},$$

or

$$PV_I = RT \frac{N}{n} \ln \frac{N + n}{N}$$

calculate the osmotic pressure for any concentration of solute from 0 to 100 percent, and may then introduce the values of osmotic pressure so found, into any convenient formula.

That such ideal solutions actually exist has been shown by Zawidski² who carried out distillations and then from the composition of the distillate calculated the partial pressure of each component in the vapor over the original solution. If the solutions are ideal, their partial pressures plotted against the liquid composition should be straight lines and this was found to be true for seven pairs of solutions: benzene-chlorobenzene; benzene-bromobenzene; benzene-ethylene chloride; toluene-chlorobenzene; toluene-bromobenzene; ethylene bromide-propylene bromide; and methylchloride-carbon dioxide. It was not true for many other pairs in nearly all of which at least one component was known to be associated.

Rosanoff and Easley³, working probably a bit more accurately, confirm this relation for benzene-ethylene chloride which is the only one of Zawidski's solutions used by them. Ten years later, Schulze⁴ reported some calculations on the vapor pressures of benzene-toluene solutions which at the lower temperatures he interprets to indicate polymerization of the toluene. At $60^{\circ}\text{C}.$ however, the total pressure over such a solution plotted against composition of the liquid is a straight line. Since this is a requirement for an ideal solution, we may conclude that, at least at 60° , benzene and toluene form an ideal solution within the limits of error of vapor pressure measurements.

In the calculations of this section, we shall assume that at 27°C benzene and toluene form an ideal solution. Whether they do or not is immaterial since they are selected merely for the sake of concreteness. Hypothetical liquids A and B, having assigned hypothetical densities, vapor pressures, and molecular weights might have been used; but the following calculations are based on an idealized benzene and an idealized toluene.

In the first column of Table V are shown the mol fractions of benzene in each solution; from this the mol fraction of the toluene can be obtained by difference. In the second column are given the osmotic pressures of benzene, calculated at 300° abs. from either Form III or Form IV, equations for the ideal solution; while the osmotic pressures of the toluene are shown in the third column.

Since the volume V_1 in the more concentrated solutions is smaller¹ than any volume into which the liquid solute can be compressed, it seemed desirable to establish a relation between osmotic pressures and the volume, V , in liters, of the solution in which one gram molecular weight of the solute is dis-

¹ Bancroft: J. Phys. Chem., 10, 320 (1906).

solved. It will be evident that the volume V , of the solution containing one mol of solute is equal to the sum of the volume of the solvent V_1 in which one mol of the solute is dissolved and the volume (M.V.) of one mol of the solute.

Or
$$V = V_1 + (\text{M.V.}) \text{ solute}$$

It should be emphasized that in doing this, we are in no way detracting from the increased applicability of $PV_1 = RT$ over $PV = RT$ for dilute solutions. Neither of these formulas is valid beyond very dilute solutions while the use of V as volume of solution in an equation exactly of the van der Waals' form,

$$(P + a/V^2) (V - b) = RT$$

expresses the osmotic pressure of either component with a deviation of less than 2% up to and including a solution containing nine mols of solute to one mol of solvent.

The fourth and fifth columns show the values of V introduced into the van der Waals equation. In calculating the osmotic pressures, the value of R was taken as 0.0820 liter atmospheres per degree instead of 0.08207. Consequently R should equal 0.0820 from the van der Waals equation and the values actually calculated are shown in columns six and seven.

The equation, then, reproduces the data satisfactorily over the range of mol fraction of solute, 0 to 0.9 though nothing short of absolute agreement can be considered really satisfactory for idealized data. By putting in more terms in the equation of state, we can of course get a better agreement. If we write

$$(P + a/V^2) (V - b - c/V^n) = RT$$

it is possible to represent the facts pretty well over the entire range of mol fractions 0 to 0.99, as is shown in Table VI).

TABLE VI

Formula applied: $(P + a/V^2) (V - b - c/V^n) = RT$

Temperature 300° abs.

For benzene as solute, $c = 2.69 \times 10^{-22}$, $n = 18.8$,

For toluene as solute, $c = 8.45 \times 10^{-22}$, $n = 27$.

These values of b so found to fit into the van der Waals equation appear to have real significance. In the first place, they are specific, for if values be introduced differing markedly from them, no value of a can be found that will make the value of R remain so nearly constant as do these accepted values.

In the second place these values appear to represent a fundamental quantity for each solute. In the case of benzene, b is 67% of the mol volume of the liquid; for toluene, the fraction is 75.3%. Similar calculations have been made with similar results for the system benzene-carbon tetrachloride. Again $b = .060$ is the value best fitting for benzene and b for carbon tetrachloride is 0.073 which is again 75% of the mol volume of the liquid carbon tetrachloride at that temperature.

The suggestion is made that these values of b may represent the actual volume of these molecules at this temperature, or, since the data are idealized, that the volume of the molecules of liquids having these densities represents this fraction of the molecular volume of the liquids. Numerous authors have shown by various methods that the b of van der Waals' equation cannot be independent of temperature and pressure so that it should not be expected that the values here used should be those values of b which are suitable for benzene as a gas at elevated temperatures. The proposed value is about one half the latter. But measurements on liquids ought to lead to this sort of fraction and they do. Tammann,¹ from measurements of compressibility of liquids at 0°, calculated for a few liquids that the volume when the pressure is infinite averages 0.718 times the volume of the liquid at 0°. Korber extended these studies on compressibilities and made some on thermal expansion for a number of liquids. These give average values for $V_{t=0} = 0.756$ and $V_{p \rightarrow \infty} = 0.72$. It is clear then, that the values of b thus satisfying van der Waals' equation as here applied have quite closely the same magnitude as these "incompressible" volumes of other methods.

Conclusions

1. Two equivalent expressions for the relation between osmotic pressures and vapor pressures have been derived in a manner analogous to that of van't Hoff. These expressions are:

$$PV_{\kappa} = \frac{RT}{M_2} \ln \frac{p_0}{p_1}$$

or

$$PV_M = RT \ln \frac{p_0}{p_1}$$

and

$$PV_I = RT \frac{N}{n} \ln \frac{p_0}{p_1}$$

2. No equation of the form $PV = RT$ can express osmotic pressures accurately. If V be defined as the volume V_I of the solvent containing one mol of solute, the data of Morse and Frazer showed the applicability of $PV_I = RT$ to be greater than that of $PV = RT$ where V is the volume of solution

¹ Ann. Physik, (4) 37, 975, 1014 (1912).

3. The heat of dilution corresponds to a work term which prevents any form of $PV = RT$ having validity over a range of concentration. The equation must be $PV = RT + f(Q)$ where $f(Q)$ is a function that cannot be evaluated at present.

4. For ideal solutions we can write $PV_I = RT$ with an error not to exceed five percent to the concentration where the solute is ten mol percent of the solution.

5. From Form II, $PV_I = RT \frac{N}{n} \ln \frac{p_0}{p_1}$, in so far as $PV_I = RT$ may be assumed to be valid, $\frac{n}{N} = \ln \frac{p_0}{p_1}$ is a general equation for the calculation of molecular weights.

6. This equation $\frac{n}{N} = \ln \frac{p_0}{p_1}$ is important because from the Clausius-Clapeyron equation $\ln \frac{p_0}{p_1} = \frac{Q}{RT^2} dT$. Substituting in this and simplifying, we get $M = \frac{Kg}{\Delta T}$ which is the equation for the calculation of molecular weights from freezing points or boiling points.

7. Raoult's law and Henry's law are shown to be essentially different, because the constant in Raoult's law is non-specific and the one in Henry's law is specific. Also because the term p_0 , the vapor pressure of the pure liquid, has no physical significance in the case of a gas above its critical temperature.

8. From the equation $PV = RT \left(\frac{N}{n} + \frac{(M.V.)_1}{(M.V.)_2} \right) \ln \frac{p_0}{p_1}$, an equation which is just as valid as Form II, in so far as $PV = RT$,

$$\frac{n}{N + \frac{(M.V.)_1}{(M.V.)_2} n} = \frac{p_0 - p_1}{p_0}$$

is obtained of the general form of Raoult's law. This may not be significant, because Raoult's law holds accurately for benzene-toluene mixtures at temperatures at which the two molecular volumes are not equal.

9. Objections to van't Hoff's relation on the ground of inadequacy have often rested upon improper definitions of the terms, especially the V of $PV = RT$.

10. Compressibility of the solvent is not a factor in measurements of osmotic pressure.

11. Some previous methods of finding the volumes of the components of a solution in the solution are discussed and it is shown that the volume of one gram of solvent in a solution may be calculated from Form I, using it as $V_s = \frac{RT}{PM_2} \ln \frac{p_0}{p_1}$. This permits the calculation of the specific volume of the solvent.

12. It has been shown that V_s for either component can be determined from the density relations, subject to a correction for possible hydrates of

varying composition. This correction is probably of slight importance when one calculates V_g for moderately concentrated solutions. Subject to this limitation, it is possible to calculate osmotic pressures accurately from a knowledge of the densities and the partial pressures.

13. The osmotic pressures of ideal solutions of benzene and toluene are calculated from either form here derived.

14. These osmotic pressures are shown to be expressed quite satisfactorily by an equation $(P + a/V^2)(V - b) = RT$ which is of the type used by van der Waals for gases.

15. The absolute validity of Raoult's law for ideal solutions gives rise to some very interesting problems in regard to mass and volume concentrations. These will be discussed in detail in a later paper.

AQUEOUS SOLUTIONS OF SODIUM SILICATES.* PART VIII.
GENERAL SUMMARY AND THEORY OF CONSTITUTION.
SODIUM SILICATES AS COLLOIDAL ELECTROLYTES.

BY R. W. HARMAN

Introduction

The interest of recent years in the ever-increasing industrial importance of sodium silicates of varying ratios $\text{Na}_2\text{O}:\text{SiO}_2$ as evidenced by their many and varied technical applications and their increased production, seems to have overshadowed the more theoretical aspect of their exact nature and behaviour in solution, from a knowledge of which we can, alone, hope to understand fully and apply more widely still this class of exceedingly puzzling but useful compound.

Although silicates generally have been subjected to extensive and prolonged investigations, sodium silicates, in particular, have received only isolated and intermittent attention. Until quite recently our knowledge of aqueous solutions of the alkali silicates was drawn mainly from the work of Kohlrausch¹, and from Kahlenberg and Lincoln,² on the electrical conductivity and from the work of Kahlenberg and Lincoln, and Loomis³ on freezing point lowering. These investigators concluded that alkali silicates are largely hydrolysed in solution, most of the silica being in the colloidal state. Later Bogue⁴ showed that the degree of hydrolysis as determined by E.M.F. measurements was unexpectedly low and not in accord with the previous conclusions drawn from measurements of conductivity and lowering of the freezing point.

The literature contains many references to several definite sodium silicates, notably Na_2SiO_3 , $\text{Na}_2\text{Si}_2\text{O}_5$, NaHSiO_3 , $\text{Na}_2\text{Si}_5\text{O}_{11}$, Na_4SiO_4 , etc. but the only one whose composition had been definitely established was the metasilicate, Na_2SiO_3 , and even then much conflicting data existed concerning the number of its hydrates. Then Morey⁵, Morey and Brown⁶ proved that Na_2SiO_3 and $\text{Na}_2\text{Si}_2\text{O}_5$ separated as crystalline salts at temperatures between $400^\circ\text{--}1000^\circ\text{C}$ from solution and from fused melts. The existence of the other sodium silicates seems more or less to have been taken for granted, as being probably formed from the great array of silicic acids postulated

*This series of papers, "Aqueous Solutions of Sodium Silicates Parts I-VIII, comprise a Thesis presented for the Degree of Doctor of Science of the University of London.

from time to time, e. g. Schwarz and Menner¹ claim the existence of at least seven silicic acids, or hydrates of SiO_2 . Our knowledge of these is, at best, very meagre and their existence as acids seems very problematical, even the mostly clearly defined of all, metasilicic acid, H_2SiO_3 , on account of its partly colloidal nature, being still wrapped in an atmosphere of mystery.

General Summary of Experimental Work and Results

In the present investigation the system $\text{Na}_2\text{O}-\text{SiO}_2-\text{H}_2\text{O}$ at 25°C has been studied along the following lines, each of which has formed the subject of a communication to this journal,—(1) preparation and conductivity, (2) transport numbers, (3) sodium ion activity, (4) hydrolysis (5) osmotic activity: lowering of F.Pt. and v.p., (6) heterogeneous equilibria (7) electrometric titration, diffusion, and colorimetric estimation of silicate.

A brief summary of the results obtained and the more important conclusions therefrom, follow seriatim.

(1) Conductivity.

From measurements of aqueous solutions of ratios 2:1, 1:1, etc. up to 1:4 we have seen² that solutions of 2:1 and 1:1 ratios are excellent conductors in dilute solution but the equivalent conductivity falls quickly with increase of concentration, so that at $2N_w$ it is relatively low. The ratios containing more silica, viz., 1:2, 1:3, and 1:4 are also quite good conductors in dilute solution and moreover the values of Δ_∞ for these three ratios are all nearly equal, being 95, 91 and 88, but in concentrated solution the conductivities are abnormally low.

Hydrolysis into NaOH and colloidal silicic acid cannot account for this high conductivity, not even with ratios relatively rich in NaOH , nor in dilute solution where hydrolysis is greatest; and with ratios rich in silica, where hydrolysis is practically negligible, it is apparent that the explanation that the conductivity is due to hydrolysis is totally inadequate.

The results obtained are reproduced again in Table I for ready reference.

TABLE I.
Equivalent Conductivity

¹ Ber., 57 B, 1477 (1924); 58 B, 73 (1925).

² J. Phys. Chem., 29, 1155 (1925).

The most reasonable assumption to explain these results is the existence of silicate ions and sodium ions due to ionisation, in addition to the NaOH formed by hydrolysis. In concentrated solution this ionisation falls off considerably or else the silicate ions are now not so active in conveying the current.

FIG. 1
Equivalent Conductivity against Ratio

From the graph where the equivalent conductivity is plotted against the ratio, as in Fig. 1, we have seen that in dilute solution there is a sharp change of direction at 1:2, the relationship on either side of this point being linear. As the solutions become more concentrated this simple relationship disappears until at $2 N_w$ the most marked changes of direction of the curves are evident at 2:1 and 1:1. It may be that definite salts of ratios 2:1, 1:1 and 1:2 exist, but in any case, concentrated solutions exhibit a radically different behaviour from very dilute solutions, suggestive of a change of state of one or more of the constituents.

(2) *Transport Numbers.*

From the results of very careful transport number experiments¹ we have seen that as the proportion of SiO_2 increases in the ratio $\text{Na}_2\text{O}:\text{SiO}_2$ so does the proportion of the current carried by the silica constituent increase. If the transport numbers are calculated on the assumption of SiO_3'' being present in all ratios, then the T.N. of this silicate ion is as shown in Table II.

From this it is fairly evident that (1) silicate ions are present and (2) that either (a) the anion may be a solvated aggregate of simple SiO_3 ions, carrying a charge equal to the sum of the total charges on the separate ions, or a solvated aggregate containing more than one mol SiO_2 per divalent charge,

TABLE II
T.N. Silicate = $\frac{\text{total change in wt. of SiO}_2 \text{ content}}{\text{wt. SiO}_2 \text{ equiv. to Ag deposited in coulometer.}}$

No. Expt.	Ratio	Approx. N _w .	n _{Na}	n _{SiO₂}	n _{OH}
1		2.36	0.27	0.17	0.56
2	1:1	1.0	0.36	0.13	0.51
3		0.1	0.31	0.18	0.51
			Mean 0.31	0.16	0.53
4		1.0	0.42	0.88	
5	1:2	0.5	0.35	0.70	
6		0.1	0.45	0.87	
			Mean 0.41	0.82	
7	1:3	1.0	0.40	1.35	
8		0.5	0.45	1.42	
			Mean 0.43	1.38	
9	1:4	1.0	0.53	2.32	
10		0.1	0.44	2.44	
			Mean 0.48	2.38	

these aggregates splitting up on dilution, or (b) the anions may be definite ions more complex than the simple ion SiO_3 ion, i.e. definite salts of the following formulae may exist, — $\text{Na}_2(\text{SiO}_3.\text{SiO}_2)$, $\text{Na}_2(\text{SiO}_3.2\text{SiO}_2)$ etc., which ionise to give definite divalent silicate ions such as, — $(\text{SiO}_3.\text{SiO}_2)''$, $(\text{SiO}_3.2\text{SiO}_2)''$, etc.

In this paper on transport numbers it was pointed out that the number of mols of SiO_2 per divalent charge (2 F) of the silicate anion seemed approximately equal to the molar ratio $\text{SiO}_2 : \text{Na}_2\text{O}$. This may be explained in two ways,—(1) ratio 1:4 e.g. may be a definite salt with a true anion of the composition $(\text{SiO}_3.3\text{SiO}_2) \text{ aq.}''$ i.e. such an anion results at any and all concentrations from ionisation, or (2) in solutions of ratio 1:4 an aggregate such as $(\text{SiO}_3.n\text{SiO}_2) \text{ aq.}''$ exists in a more loosely bound combination, in such a way

¹ J. Phys. Chem., 30, 359 (1926).

that "n" may be large in very concentrated solutions, but in very dilute solutions smaller and even zero, though in the range of concentration measured, as far as experimental conditions allow, it appears on an average equal to four. In such circumstances it was concluded not to be so misleading to calculate the T. N. of the silicate anion from

$$\text{T. N. Silicate} = \frac{\text{total change in wt. of SiO}_2 \text{ content}}{N \times (\text{wt. of SiO}_2 \text{ equiv. to Ag deposited in coul.})}$$

and the results obtained are given again in Table III.

TABLE III
Transport Numbers

N	Ratio	n_{Na}	n_{Si}	n_{OH}
1	1:1	0.37	0.16	0.53
2	1:2	0.41	0.41	0.18
3	1:3	0.43	0.46	0.11
4	1:4	0.48	0.59	—

(3) *Sodium Ion Activity.*

The measurements of sodium ion activity by means of a sodium amalgam electrode¹ were carried out in the hope of gaining some idea of the sodium ion concentration in solutions of these various ratios. The results with ratio 1:1 however, were anomalous in that the curve of γ , the activity coefficient, against concentration, passed through a minimum at moderate concentration, about $0.1N_w$, and so caused some irregularity, but the results obtained with the higher ratios did not show similar behaviour. The activity coefficient, from being comparatively high in dilute solution, changed regularly to a very low value in concentrated solution, being more or less parallel to the conductivity. The fall in γ as the proportion of SiO_2 in the ratio $\text{Na}_2\text{O} : \text{SiO}_2$ increased was also fairly regular.

TABLE IV
Sodium Ion Activity

Conc. N_w .	γ = activity coefficient			
	1:1	1:2	1:3	1:4
1.0		0.265	0.105	0.050
0.80	0.475	0.275	0.145	0.060
0.50	0.440	0.310	0.185	0.090
0.40	0.425	0.335	0.210	0.110
0.20	0.415	0.410	0.295	0.185
0.10	0.425	0.460	0.365	0.250
0.05	0.500	0.500	0.425	0.325
0.025	0.700	0.525	0.480	0.405
0.01	0.975	0.785	0.700	0.550

¹ J. Phys. Chem., 30, 917 (1926).

The general conclusions can be drawn that increase of concentration for any one ratio, and especially increase of silica in the ratio, both have a very marked effect on the activity of the sodium ion, so reducing it that in concentrated solutions of ratios 1:3 and 1:4 it is remarkably and unexpectedly low.

The results obtained are summarised in Table IV.

FIG. 2

Sodium Ion Activity, γ , against Concentration

These results are shown graphically in Fig. 2.

(4) *Hydrolysis.*

The description of E. M. F. measurements of hydrogen ion concentrations is given in Part IV of this series¹ the chief results of which are summarised in Table V.

TABLE V
Percentage Hydrolysis

N_w	2:1	1:1	1:1.5	1:2	1:3	1:4
2.0	17.5	15.25	3.0	1.0	0.101	0.032
1.0	19.0	16.5	5.9	1.35	0.192	0.071
0.5	19.7	19.1	7.10	1.88	0.36	0.14
0.2	24.2	20.0	8.25	2.40	0.58	0.35
0.1	28.4	21.8	8.7	2.85	0.77	0.57
0.05	31.6	22.6	9.76	3.8	1.10	0.93
0.02	34.2	23.25	11.0	5.1	1.20	1.30
0.01	36.0	27.8	12.0	6.5	1.34	1.50

¹ J. Phys. Chem., 30, 1100 (1926).

These results are shown graphically in Fig. 3.

It was there shown that the degree of hydrolysis and the concentration of OH ion are in a measure proportional to the proportion of Na_2O in the ratio. The great point of interest however, is that even in very dilute solution ratio 1:1 shows only 27.8% hydrolysis, while ratios 1:3 and 1:4 only about 1.5% hydrolysis. In concentrated solution the degree of hydrolysis is even more remarkably low, being 15% and 0.1 and 0.03% respectively for concentration

FIG. 3
Percentage Hydrolysis against Concentration

2N_w. We thus see that hydrolysis can in no way explain the conductivity of these silicate solutions. If, as some later investigators have assumed, the OH ion concentration, as here calculated from measurements by the hydrogen electrode, does not give the true value of the hydrolysis, then OH ion adsorption by the colloidal silica takes place to a very large extent, especially in the higher ratios. Hence these solutions should show a very low osmotic activity, which they do not, a point to be dealt with more fully later in considering results of measurements of F.Pt. lowering. The only other explanation seems to be that silica exists in the crystalloidal state in solution, some possibly as silicate ions, and is not wholly colloidal as heretofore supposed.

From Table I¹ (Part IV) giving the values of the liquid-liquid potential difference sodium silicate/sat. KCl, as experimentally determined by the Bjerrum extrapolation method, in ratios 2:1 and 1:1 this liquid-liquid P.D. is of the order of 3-4 millivolts and opposes the general E. M. F. of the cell, as expected from a moderate concentration of OH ions. In ratios 1:3 and 1:4

¹ J. Phys. Chem., 30, 1100 (1926).

the P. D. is just as large but is in the opposite direction. Here the OH ion concentration is practically negligible, hence the silicate ion is less mobile than the sodium, or there is a greater concentration of sodium ions present.

We have seen, too, that when the percentage hydrolysis is plotted against the ratio somewhat similar changes of direction occur as when the conductivity is plotted against the ratio, and the conclusion was drawn that the variation in conductivity noted, in the more concentrated solutions of ratios containing little silica, are mainly due to changes in the OH ion concentration.

FIG. 4
Molecular Depression of Freezing Point against Concentration

(5) Osmotic Activity.

Lowering of vapour pressure and freezing points.

In Part V of this series¹ are described measurements of the lowering of the vapour pressure and of the freezing point, the results summarised below being presented from the point of view of both the earlier ionic theory, Table VI, and from the more recent activity theory, Table VII.

These results are shown graphically in Fig. 4.

These results show us that for ratio 1:1 both modes of calculation indicate that at concentration 0.01 N_w dissociation into 4 ions or active constituents is nearly complete and accounts for the conclusions of early investigators that Na_2SiO_3 was almost completely hydrolysed according to the following equation,—

¹ J. Phys. Chem., 31, 355 (1927).

TABLE VI
Lowering of the Freezing Point

N _w	m	Van't Hoff factor "i".				
		2:1	1:1	1:2	1:3	1:4
2.00	1.00	2.30	1.98	1.03	0.772	0.565

0.10	0.05	3.85	3.13	2.74	2.36	2.13
0.05	0.025	4.35	3.55	3.01	2.73	2.69
0.02	0.01	5.05	3.75	3.22	2.96	2.96
0.01	0.005	5.60	3.87	3.55	3.22	3.01

TABLE VII
Activity Coefficient, from F. Pt. based on $\nu = 4$, i.e. the molecule gives 4 ions at infinite dilution

m	NaOH	1:1	1:2	1:3	1:4
0.005	0.950	0.922	0.731	0.604	0.412
0.010	0.920	0.888	0.599	0.484	0.342
0.025	0.867	0.778	0.456	0.359	0.244
0.050	0.820	0.626	0.358	0.252	0.171
0.100	0.765	0.497	0.259	0.179	0.109
0.500	0.700	0.280	0.080	0.052	0.029
1.000	0.680	0.192	0.035	0.029	0.015

But this view is no longer tenable, as not being in accord with the percentage hydrolysis as directly measured. In the paper on hydrolysis (*loc. cit.*) it was shown that ratio 1:1, i.e. the metasilicate, Na_2SiO_3 , undergoes on solution both ionic and hydrolytic dissociation giving rise to Na , OH and SiO_3 ions and crystalloidal H_2SiO_3 , at least in dilute solution.

It was there shown, too, that, as far as hydrolysis, sodium ion activity, and freezing point lowering results are concerned, it appeared very probable that the acid salt NaHSiO_3 exists in solution. Ratios 1:3 and 1:4 on the other hand do not appear to be definite salts and their behaviour in solution is quite remarkable, e. g. the van't Hoff factor "i" for ratio 1:4 ranges from 0.565 for 2 N_w to 3.01 for 0.01 N_w, while the activity coefficient ranges from 0.015 to 0.412 for the same concentrations respectively. To explain this it was there tentatively put forward that the results from ratios 1:3 and 1:4 seemed to suggest the possibility of complex colloidal aggregates in very concentrated solution, and of ionic micelles in moderately concentrated solutions, such ionic micelles breaking up on dilution somewhat after the manner indicated by the following equations,—

(6) *Heterogeneous Equilibria.*

System: $\text{Na}_2\text{O} : \text{SiO}_2 : \text{H}_2\text{O}$ at 25°C .

In this paper¹ (Part VI) it was shown that only two salts corresponding to ratios 1:1 and 1:2 exist at 25°C . Ratio 1:1 is undoubtedly the metasilicate, Na_2SiO_3 , and its hydrates have been shown to contain 9, 6 and 2.5 aq respectively. Ratio 1:2 may be either $\text{Na}_2\text{Si}_2\text{O}_5$ or NaHSiO_3 , but in any case should crystallise out with the composition $\text{Na}_2\text{O} . 2\text{SiO}_2 . 9\text{H}_2\text{O}$.

No evidence for the existence of any other than salts corresponding to these two ratios was found.

Attention was drawn in this paper to the fact that Morey had previously obtained Na_2SiO_3 and $\text{Na}_2\text{Si}_2\text{O}_5$, and these two only, but his $\text{Na}_2\text{Si}_2\text{O}_5$ was not readily affected by water. It was also noted that both Niggli and Wallace failed to obtain a definite salt richer in silicate than the metasilicate.

(7) *Silicate Ions and Crystalloidal Silica.*

The problem of obtaining some definite knowledge on this aspect of the problem is treated in Part VII of this series² but only in a meagre preliminary manner.

The electrometric titration curves of a dilute HCl solution against dilute Na_2SiO_3 solutions are typical of dibasic acids, thus suggesting H_2SiO_3 as a true dibasic acid with salts NaHSiO_3 and Na_2SiO_3 ; the dissociation constants being given as $k_1 = 4.2 \times 10^{-10}$ and $k_2 = 0.51 \times 10^{-16}$.

The results from a few diffusion experiments indicate that most of the silica in ratios 1:1 and 1:2 is diffusible, about $\frac{2}{3}$ of the silica in 0.3N 1:4 and about $\frac{1}{3}$ in 0.1N H_2SiO_3 being crystalloidal.

In this paper, also, a colorimetric method of estimating crystalloidal silica by means of H_2SO_4 and ammonium molybdate showed that the amount of crystalloidal silica in any ratio was directly proportional to and expressed by the same figure as the ratio $\text{SiO}_2:\text{Na}_2\text{O}$ in extremely dilute solution.

Theoretical

An attempt will now be made to correlate the data obtained and to present an explanation of the constitution and of the behaviour in aqueous solution of the various $\text{Na}_2\text{O}:\text{SiO}_2$ ratios investigated. Attention will be chiefly focussed on the evidence adduced in proof of the following four main statements,—

(1) Silica exists in solutions of these ratios not wholly colloidal as heretofore supposed, but wholly or partly as crystalloidal silica depending upon the ratio $\text{Na}_2\text{O} : \text{SiO}_2$ and upon the concentration. This crystalloidal silica existing in equilibrium with silicate ions, or electrically charged aggregates of silicate ions and silica i.e. ionic micelles, or pure colloidal aggregates, as the case may be, depending upon the ratio and concentration.

¹ J. Phys. Chem., 31, 511 (1927).

² J. Phys. Chem., 31, 616 (1927).

(2) In aqueous solution at 25° C two and only two simple salts viz., Na_2SiO_3 i.e. ratio 1:1, and NaHSiO_3 i.e. ratio 1:2, appear to exist as such, the behaviour and nature of which are now elucidated.

(3) Ratios other than 1:1 and 1:2 are not definite salts but are typical examples of colloidal electrolytes.

(4) The fundamental nature of silica in solution appears to depend upon the existence, at least in the range here investigated, of only one acid, **meta-silicic acid**, in which the equilibrium between the crystalloidal and the colloidal constituents depends upon the concentration, the crystalloidal content at ordinary concentrations being much greater and the acid, therefore, much stronger, than generally supposed.

Evidence for the Existence of "Crystalloidal" Silica¹

Under the heading "crystalloidal silica" are classed definite silicate ions, aggregates of ions carrying an electric charge with or without some colloidal silica, i.e. ionic micelles, and crystalloidal silicic acid or hydrated silica. The evidence produced herein, for the existence of such crystalloidal silica, rests mainly on the following four sources,—

(1) Conductivity measurements resulted in the finding of a much greater conductivity for ratios up to 1:2 than could result alone from the proportion of NaOH formed by hydrolysis, as measured by the E. M. F. method. Above ratio 1:2 where the hydroxyl ion concentration is very low, the sodium ion accounts for about only one-half the conductivity found. The only way to account for the conductivity is to postulate the existence of silicate ions with mobilities ranging from 40-60 approximately. Moreover, the equivalent conductivity, as calculated from the concentration of sodium, hydroxyl and silicate ions as found from F. Pts., OH and Na ion measurements, and their respective mobilities, agrees well with the experimentally determined conductivity.

(2) The most direct and conclusive evidence so far put forward to show that the silica in aqueous solutions of these ratios carries an electric charge is obtained from the results of transport number experiments. From these it was shown that $n_{\text{sil}} = 0.16$ for ratio 1:1, 0.41 for ratio 1:2, 0.46 for 1:3, and 0.59 for 1:4, when calculated by the second method. Whether this basis of calculation is correct or not, these transport number experiments proved that quite a fair proportion of the current, at least one-half in the higher ratios, is carried by the "silica." Since the possibility of adsorbed hydroxyl ions on the silica giving the necessary charge to the silica, has been shown to be remote and indeed most improbable, the only conclusion is that the silica must exist as ions. The relatively high mobility of these charged silica particles as deduced from conductivity and transport number results, is also contrary to that expected from colloidal aggregates with OH ions adsorbed thereon.

(3) A third very weighty argument appears when we consider the result of hydrolysis experiments along with freezing point lowering results. In

¹ In this paper the word "crystalloidal" is used to denote constituents which are "osmotically and ionically active."

the paper on osmotic activity it was shown that the only possible way to account for the high osmotic activity of these ratios in aqueous solution was to accept the existence of silicate ions. The conductivity of the sodium ions and of the hydroxyl ions as found by E. M. F. experiments, together account for only a fraction of the total ion concentration as determined by freezing point lowering. The non-accordance is quite beyond the bounds of experimental error, nor could it be accounted for by the assumptions underlying the laws governing ideal solutions. The higher the ratio the wider is the divergence, so that in 1:3 and 1:4 more than half the "crystalloidal" content has to be accounted for by the silica in the more dilute solutions. Whether this is due to the complex silica aggregates breaking down into simpler silicate ions, or to the disintegration of an ionic micelle, or to crystalloidal H_2SiO_3 ionising, or to all these phenomena, will be discussed later. The fact remains, however, of a very large proportion of crystalloidal silica in solution, more especially in dilute solution.

(4) Direct evidence of the existence of crystalloidal silica is put forward in Part VII of this series, giving the results of diffusion experiments with colloidion membranes and parchment paper, and the results of a colorimetric estimation for crystalloidal silica based on the formation of silicomolybdate. The diffusion experiments indicated that most of the silica in ratios 1:1 and 1:2 is diffusible; about $\frac{2}{3}$ of the silica in 0.3 N_w 1:4 and about $\frac{1}{3}$ in 1.0 N_w H_2SiO_3 also being crystalloidal. The silicomolybdate colorimetric test showed that in very dilute solution, 0.001 N_w , the amount of crystalloidal silica as compared with that in ratio 1:1 i.e. sodium metasilicate, was directly proportional to the ratio.

The existence of crystalloidal silica and silicate ions in aqueous solution seems therefore firmly established, and there now remains the problem of what nature and composition are the ions and charged aggregates, and in what proportions they exist. In the solution of this problem the nature and composition of the salts giving rise to these ions furnish a good guide, and help to narrow down the possibilities.

Ratios 1:1 and 1:2 are Definite Salts. Their behaviour in solution.

From the investigation of the ternary system $\text{Na}_2\text{O} : \text{SiO}_2 : \text{H}_2\text{O}$ at 25°C we have seen that only ratios 1:1 and 1:2 occur as definite solid salts. Ratio 1:1 is the metasilicate Na_2SiO_3 , crystallising with 0, 6 and 2.5 aq., the existence of which has long been established, in spite of the difficulty of its crystallisation and the confusion which till now has existed concerning its hydrates.

A certain amount of evidence that these two ratios correspond to definite salts in solution is also forthcoming from consideration of the curves where conductivity, hydroxyl ion concentration, sodium ion concentration, and the van't Hoff factor "i" (from freezing points) are severally plotted against the ratio, distinct changes of direction at these points being evident. It was also seen from consideration of freezing point results that the existence of salts corresponding to ratios 1:3 and 1:4 was very unlikely.

From these results of the phase rule investigation we have seen that the following solid salts would be expected to separate from solution,—

(1) $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$. This salt has been obtained by the author not only from alcoholic solution, but also in the form of large, well-defined crystals from a 2 N_a solution of ratio 2:1 without the addition of alcohol or inoculating crystals.

This decides the hitherto conflicting and confusing data concerning the hydrates of Na_2SiO_3 .

(2) $\text{Na}_2\text{O} \cdot 2\text{SiO}_2 \cdot 9\text{H}_2\text{O}$. This compound has so far resisted all attempts at separation in a pure form from aqueous solution at 25°C. It may be from the phase rule results, either $\text{NaHSiO}_3 \cdot 4\text{H}_2\text{O}$ or $\text{Na}_2\text{Si}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$.

Ratios 1:3 and 1:4.

We have seen that only the ratios 1:1 and 1:2 exist as definite silicates and there now remains an explanation of ratios 1:3 and 1:4.

The fact that there is increasingly less percentage hydrolysis as the proportion of silica increases in the ratio until it is practically negligible in 1:4 favours very much the view that these higher ratios are complexes of the two beforementioned salts with excess of silicic acid, or hydrated silica, the presence of the silicic acid, one of the products of hydrolysis of these two salts, causing the diminution in hydrolysis according to the law of mass action.

Again, if either of the ratios 1:3 or 1:4 were definite salts, then, since, hydrolytic decomposition seems negligible, 100% ionisation into three ions would not be sufficient to account for the large molecular depression of the freezing point in dilute solution. However, sodium ion activity measurements indicate that in dilute solution 70% in ratio 1:3 and only 55% in 1:4 is the extent to which the sodium exists as active sodium ions. To bring the results from F. Pt. measurements and from sodium ion measurements into agreement would necessitate, since only sodium and silicate ions are present, in the case of ratio 1:3 approximately 80% ionisation into 4 ions, and in 1:4 approximately 60% ionisation into 5 ions. It appears quite improbable that any simple salt of composition corresponding to ratio 1:3 i.e. $(\text{Na}_2\text{O} \cdot 3\text{SiO}_2 \cdot \text{aq.})_n$ could ionise into 4 ions or any corresponding to 1:4 i.e. $(\text{Na}_2\text{O} \cdot 4\text{SiO}_2 \cdot \text{aq.})_n$ into 5 ions. Nor would it be a reasonable hypothesis even to assume the existence of such problematical compounds when all the evidence (except for the results of experiments on transport numbers) from the other lines of investigation employed, goes against the existence of these higher ratios as definite salts.

Thus an explanation on quite different lines must be sought, and a most rational one follows when we consider these ratios as colloidal electrolytes from the viewpoint of aggregate or micelle formation.

Silicates as Colloidal Electrolytes

In very concentrated solution the silicate probably exists as a very complex aggregate, which not only breaks up into similar simple aggregates on dilution but also gives rise to sodium and SiO_3 ions and ionic micelles, in some such manner as the following, =

The following equilibria also existing in the more dilute solution

where aggregates included in square brackets are colloidal.

Dilute Solution 1:4.

Since $\gamma = 0.55$ at concentration $N_w = 0.01$ from sodium ion activity measurements, and since there must be two sodium ions for each SiO_3 ion or $(\text{mSiO}_3 \cdot \text{nSiO}_2 \cdot \text{aq})^m$ aggregate, the total normality of ion constituents is thus $3 \cdot N_w \cdot \gamma = 0.0165 N_w$. But the total crystalloidal content is $0.03 N$ from F. Pt. measurements, so there is still $0.0135 N$ crystalloidal content to account for. Part of this is no doubt due to the unionised $(\text{Na}_2\text{O} \cdot 3\text{SiO}_2 \cdot \text{aq})$ which at this dilution may be supposed broken down into a more or less simple or crystalloidal condition. If it were all so i.e. $0.0045 N$ in this simple state there is still $0.009 N$ crystalloidal matter to account for. The only rational assumption to account for this $0.009 N$ crystalloidal matter is to consider it a simple or unionised hydrated silica or silicic acid, probably H_2SiO_3 , as postulated in equation (3) above. This means that $\frac{0.009}{0.04} = 0.225$ or 22.5% of the total

silica is in the form of H_2SiO_3 . If none of the unionised $(\text{Na}_2\text{O} \cdot 3\text{SiO}_2 \cdot \text{aq})$ is in a simple crystalloidal condition then there is $0.0135 N$ silicic acid i.e. 0.34 or 34% of the total silica present.

Thus at concentration $0.01 N_w$ 1:4 ratio, we have approximately 34% of the total silica in the crystalloidal form of H_2SiO_3 , and 14% in the crystalloidal form of ions or ionic micelles, i.e. about 50% as crystalloidal silica. This amount of crystalloidal and colloidal silica, 50%, receives direct support from the colorimetric estimation of crystalloidal silica in the form of silicomolybdate, (paper VII) where it was shown that about 75% of the silica is crystalloidal at concentration $0.007 N_w$ ratio 1:4.

Dilute Solution 1:3.

Similarly for a $0.01 N_w$ solution 1:3, we get a total crystalloidal content of $0.032 N$ from F. pts., and a crystalloidal content of 0.014 for sodium ions from activity measurements, leaving $0.018 N$ to be accounted for by the silica content of $0.03 N_w$. Thus $\frac{0.012}{0.030}$ or 40% of the total silica is colloidal.

The colorimetric estimation shows that nearly 20% of the total silica is colloidal at concentration $0.007 N$, so here also the colorimetric method gives a lower value, due no doubt to the error incurred in attempting to measure these relatively high concentrations by its means.

Moderately Concentrated Solutions.

It was for concentrations 1.0-0.1 N_w that the transport numbers were found and from which we concluded that in ratios 1:3 and 1:4 there were three and four equivalents SiO_2 respectively, per electric charge. It is in these solutions that the micelle or aggregate would evidence itself if it existed.

From sodium ion measurements 25% of the total sodium is in an active ionic form and hence 25% of the total silica is also in an active ionic form, presumably $(mSiO_3 \cdot nSiO_2 \cdot aq)^{m-}$ from transport experiments: these two giving rise to 0.075 N crystalloidal matter, leaving 0.155 $N =$ crystalloidal matter to be accounted for by the remaining 0.3 N_w silica and 0.075 N_w sodium content, which means that about 50% of this remaining silica or 30% of the total silica is in the colloidal form associated probably with sodium.

From diffusion experiments we have seen that about $\frac{1}{3}$ of the total silica is in the colloidal form at concentration 0.3 N_w 1:4. Although the results obtained and the calculations and conclusions therefrom given above, do not afford absolute and conclusive proof of the two fundamental suggestions upon which this theory of the behaviour of sodium silicates in solution rests, viz., (1) the existence of a micelle or aggregate of the composition $(mSiO_3 \cdot nSiO_2 \cdot aq)^{m-}$ (2) simple unionised crystalloidal hydrated silica, H_2SiO_3 , or other silicic acids, yet considering all the experimental evidence to date one is forced to acknowledge that only along some such lines can the behaviour of these solutions be explained.

The reasons for assigning such a constitution as the above to these silicate solutions are briefly recapitulated again,—(1) no evidence has been found experimentally to show that definite salts corresponding to ratios 1:3 and 1:4 in particular, and to the ratios higher than 1:2 in general, exist in solution at 25°C (2) the transport numbers indicate that the number of mols of SiO_2 per divalent charge is approximately numerically equal to the ratio $Na_2O : SiO_2$.

(3) The conductivity in dilute solutions is very good and as there is no (OH) ion and the sodium ion accounts for a little less than half of the conductivity, silicate ions or charged aggregates of fairly large mobility must exist.

(4) In concentrated solution the conductivity, sodium ion concentration, crystalloidal content (from freezing-points measurements) are all most abnormally low, yet all surprisingly high in dilute solution, such that ionisation into sodium ions and equivalent silicate ions, as measured by the sodium ion concentration, shows a serious discrepancy with freezing point lowering results, unless we consider that complex silicate ions or micelles exist in the stronger solution and split up into simpler crystalloidal states in dilute solution.

(5) A fair agreement exists between the relative amounts of colloidal and crystalloidal silica calculated from the osmotic activity measurements on the two assumptions of the existence of a micelle and crystalloidal silica, and those found directly by colorimetric estimation and by diffusion.

(6) Simple unionised crystalloidal silicic acid has been shown to exist at much higher concentration than usually granted; it is also a much stronger acid than hitherto supposed.

(7) The widely recognised property of silicon or silica and its hydrates to form complexes, molecular compounds and aggregates, colloidal solutions and gels, would seem to be in agreement with the conclusions here set forth.

Concentrated Solutions.

The concentrated solutions of these ratios are characterised by a very low conductivity, practicable negligible hydrolysis, very low sodium ion concentration, abnormally low molecular depression of the freezing-point, very high viscosity, and non-diffusibility, facility to form the gel condition etc., in fact getting more and more typically colloid either with increase of concentration or with increase of SiO_2 in the ratio.

The theory here outlined affords a good explanation of this, in fact it is necessary only to recall that at the lower concentrations we have seen that the equilibria represented by equations (1), (2) and (3) at the head of this section all show a tendency to go from right to left with increasing concentration in any one ratio, and with increasing ratio $\text{SiO}_2 : \text{Na}_2\text{O}$ at any one concentration.

Such being the case it is a natural consequence to expect solutions of any ratio to become more and more colloidal as the concentration increases and to expect the colloidal properties to be evidenced earlier and in more marked respect the higher the ratio.

The transition from a typical colloid, through the colloidal electrolyte stage to a good electrolyte is very well shown by ratio 1:4 on diminishing the concentration. Ratio 1:3 also shows the transition well and it seems permissible to carry the analogy to the lower ratios, where it is seen to offer the best explanation of the very viscous solutions of ratio 1:1 and its low conductivity and osmotic activity.

Summary

(1) A summary is given of the results and conclusions of seven preceding papers on the aqueous solutions of sodium silicates of ratios 2:1 to 1:4 at concentrations ranging from 0.001 N_w to 2.0 N_w , from the points of view of conductivity, transport numbers, sodium ion activity, hydrolysis, osmotic activity, phase rule, and crystalloidal silica.

(2) The various data have been correlated and an explanation given of the constitution and behaviour in aqueous solution of these silicates.

(3) The evidence for crystalloidal silica and silicate ions has been recapitulated.

(4) Ratios 1:1 and 1:2 only are definite salts viz., Na_2SiO_3 and NaHSiO_3 and their percentage hydrolysis and ionisation have been found and shown to agree with the various measurements, thus affording a complete explanation of their behaviour in solution.

(5) Above ratios 1:2 colloidal silica is in evidence, the proportion of colloidal silica increasing with the concentration and the ratio $\text{SiO}_2 : \text{Na}_2\text{O}$.

(6) In dilute solutions of ratios above 1:2 crystalloidal uncharged silica probably H_2SiO_3 or simple hydrated silica occurs.

(7) These ratios higher than 1:2 exhibit properties characteristic of colloidal electrolytes with a micelle of the composition $(m\text{SiO}_3 \cdot n\text{SiO}_2 \cdot aq.)^m$

where $\frac{m+n}{m} = \text{ratio SiO}_2/\text{Na}_2\text{O}$.

(8) In concentrated solutions of the higher ratios a large colloidal aggregate exists, containing both sodium and silica.

(9) Silicic acid has been shown to be stronger than usually supposed, its dissociation constants being of the order 10^{-10} and 10^{-16} .

I wish to express my thanks to the Commissioners of the 1851 Exhibition for a scholarship which has enabled me to carry out this work, and to Professor Donnan for his constant, kindly interest and advice.

THE HEATS OF VAPORIZATION OF ISO-PROPYL ALCOHOL AND ETHYL ALCOHOL

BY GEORGE S. PARKS AND WILLIAM K. NELSON

A few years ago, in connection with another research, some information was needed concerning the heat of vaporization of iso-propyl alcohol. At that time the only two values existing in the literature were those of Luginin¹ and Brown.² The former reported a result of 157.8 cal. per gram; the latter obtained a mean value of 161.1 in a very careful and noteworthy investigation of the heat of vaporization of a number of substances. It seemed to us probable that these earlier investigators may have been seriously handicapped in obtaining accurate values by the difficulty attached to securing any large amount of pure iso-propyl alcohol. At any rate there is a 2% discrepancy between their results; and, in view of this situation, the present determination was undertaken. As will be shown subsequently in this paper, our mean result is 161.7 cal. per gram.

In making the determinations to be described, ethyl alcohol was used for preliminary measurements in order to test the apparatus and to aid in remedying any sources of error that might become apparent. This was done because the supply of ethyl alcohol was more plentiful than that of iso-propyl alcohol. However, it was found that the values previously obtained for the heat of vaporization of ethyl alcohol showed great divergence, so after the development of our method two complete series of runs were made upon this substance. Our mean result in this case was 208.7 cal. per gram.

Following the completion of our work, Mathews³ has recently published the data of a very interesting investigation on the heat of vaporization of a large number of liquids. For iso-propyl alcohol he obtained 159.23 and for ethyl alcohol 201.88 cal. per gram at the respective temperatures, 81.25° and 77.42° C.

Experimental

Materials. Commercially refined iso-propyl alcohol and ethyl alcohol served as the starting point in the preparation of the materials for the present investigation. Water being the chief impurity, these were first dehydrated by three successive treatments and distillations with lime in the ordinary manner. The resulting liquids were then carefully fractionated. In each instance the middle fraction, about 60% of the total, was selected for use in the measurements. It showed a density of 0.78108 25°/4° in the case of iso-propyl alcohol and of 0.78549 25°/4° for ethyl alcohol. On the basis of the criteria⁴ previously employed, these values correspond to a purity of 99.90% and 99.86%, respectively.

¹ Luginin: *Ann. Chim. Phys.*, (7) **13**, 340 (1898).

² Brown: *J. Chem. Soc.*, **83**, 991 (1903).

³ Mathews: *J. Am. Chem. Soc.*, **48**, 572 (1926).

⁴ Parks and Kelley: *J. Phys. Chem.*, **29**, 728 (1925).

Apparatus and Procedure. In principle, the method was simple. It consisted essentially of supplying measured quantities of heat electrically to the alcohol, which previously had been brought to its boiling point, and of condensing and weighing the amount thereby vaporized. Thus, a careful weighing of the amounts vaporized per 15-minute period at two known rates of energy input gave, by difference, the necessary data for the calculation of the heat of vaporization.

The apparatus, as finally developed after much preliminary experimentation, conformed closely to the second type described by Awbery and Griffiths.¹ A 2.5-liter, silvered, Dewar vessel served as the container for the alcohol which was to be vaporized. This vessel was of a carafe or bottle shape with a neck about 12 cm. long. Thus, with the carafe half-filled with liquid, the vapor produced had to pass vertically upward at least 20 cm. before escaping into the outlet tube. This distance should greatly reduce any error due to the production of spray and the consequent loss of liquid as such. The heating coil in this evaporator consisted of 1.5 meters of No. 30 (B. and S.) enameled Therlo wire, wound upon a small mica frame; it had a resistance of about 14 ohms. The carafe was fitted with a cork stopper (tin-foiled) which carried the mercury-filled glass tubes leading to the heating coil, a glass tube closed at the lower end and containing a thermocouple junction for measuring the temperature of the liquid, and a 12 mm. Pyrex outlet tube for the vapor. The last ran through the stopper vertically, then turned sharply downward at an acute angle and passed out through an opening in the outer jacket to connect with an inclined condenser.

Surrounding this Dewar evaporator was the outer container or thermostat, which was a vapor-tight, cylindrical vessel of copper about 60 cm. high and 20 cm. in diameter. It was jacketed with a layer of asbestos sheeting. The upper half of this container was then wound with a few turns of high resistance wire to serve as a heating coil and covered with another layer of sheeting. A form, wound with more resistance wire, covered the top of the cylinder. These coils, placed in parallel with one another but in series with a variable resistance, were supplied with a suitable current from the 110-volt line. The outer container was ordinarily filled to a depth of about 3 cm. with some of the same alcohol employed in the evaporator. During the vaporization measurements this liquid was heated and kept at its boiling point by means of a Bunsen burner placed directly beneath the cylinder, which rested upon a small iron tripod. To conserve the resulting vapor, the outer container was equipped with a reflux condenser, the connecting tube being large enough to insure smooth boiling and the easy return of condensed alcohol. The Dewar evaporator, being a commercial vacuum bottle, came supplied with a small metal jacket and this was left on in the present case to prevent any of the cooled condensate from coming into direct contact with the glass vessel.

In addition to the openings for the outlets to the two condensers, there were two more openings in the copper cylinder for the lead wires to the heat-

¹ Awbery and Griffiths: Proc. Phys. Soc. London, **36**, 309 (1924).

ing coil within the evaporator. Two wires were led in through each of these two openings. One pair of wires carried the current from the lead storage battery and the other pair connected with the voltmeter which was used to measure the fall of potential across the heating coil. All openings in the outer container were reinforced by soldering in short pieces of copper tubing of such diameters that standard rubber stoppers gave very tight seals. The lead wires were introduced through these stoppers as were also the glass outlet tubes for the liquid. The container was fitted with a leak-proof cover.

A flat wooden block was used as a stand for the Dewar evaporator inside the copper cylinder. This block was drilled in several places to permit free circulation of the bath liquid. As noted before, the outer container was mounted upon an iron tripod stand. The condensers were supported by large iron ringstands.

A large piece of asbestos was formed into a cylindrical screen about 90 cm. high and 40 cm. in diameter. Holes were made in this screen for the lead wires and the outlets to the condensers, and it was then placed around the entire apparatus. A circular piece of asbestos sheeting was used to cover the top.

The copper-constantan thermocouple wires were led into the outer container through the reflux condenser and from there to the tube in the stopper of the Dewar carafe. The other junction was placed in a mixture of ice and water. The e. m. f. readings were made with a Leeds and Northrup "thermocouple" potentiometer. The voltmeter employed for determining the fall of potential across the heating coil in the evaporator was a Weston instrument, reading to 0.01 volt. The ammeter, in series with the coil, was of German manufacture and could be read to 0.001 ampere. The time elapsing during the collection of a sample of the condensed vapor was measured by a stopwatch. The voltmeter ammeter and watch were carefully calibrated at the time of the determinations and probably gave values for the energy input accurate to within 0.3%.

The actual procedure in making the measurements of the heats of vaporization was extremely simple. The evaporator was about half filled with the particular alcohol under investigation. Enough of the same material was kept in the outer container to prevent it from becoming dry through evaporation losses, although the level was always maintained below the bottom of the Dewar carafe. The quantities of liquid in the two vessels having been satisfactorily arranged, the apparatus was heated up to the boiling point of the alcohol. To accomplish this the outer container was heated by means of the Bunsen burner and the external heating coils, while heat was supplied to the alcohol in the carafe by an electric current from a 20-volt storage battery discharging through the Therlo coil. After the condensate from the evaporator began to flow at a uniform rate and the thermocouple gave a reading corresponding to the boiling point of the alcohol, the applied voltage was reduced to approximately two volts. A half-hour was allowed to elapse, in order that equilibrium might be attained, and then the condensate was collected in small Erlenmeyer flasks and weighed. In each set of determina-

tions five portions were collected at this voltage, fifteen minutes being the duration of each collection period. The voltage was next increased to the figure at which the measurement was to be made, and another half-hour was devoted to securing equilibrium. At the end of this interval the condensate was again collected over fifteen minute periods and weighed. Eight or nine portions were usually taken during a series of the determinations, great care being exercised to change the flasks at exactly the end of the fifteen minute periods without loss of liquid. The voltmeter and ammeter were read at one minute intervals during the collection of each sample of condensate and the average of these readings was taken for the calculations. The energy input at two volts and the amount of liquid collected at this voltage were used as reference quantities; the values thereby obtained were subtracted from those found for the higher voltages. Under these experimental conditions there could be but little energy exchange between the evaporator and its surroundings and the residual effect was allowed for by thus determining the energy required to produce a very slow rate of evaporation.

Results. The individual results obtained in one of the series of determinations on iso-propyl alcohol are recorded in Table I. In order to show the calculation involved, it may be well to indicate the steps taken to find the first of these:

Average lower voltage	1.940 volts
Average lower current	0.141 amps.
Average condensate at lower voltage	0.700 gms.
Average higher voltage	13.585 volts
Average higher current	0.987 amps.
Condensate at higher voltage	18.158 gms.
Time of collecting sample	900 seconds

$$\text{Heat of vaporization} = \frac{[(13.585)(0.987) - (1.940)(0.141)](2391)(900)}{(18.158 - 0.700)}$$

$$= 161.9 \text{ cal./gm. (preliminary value).}$$

To correct for the current passing through the voltmeter circuit and for the heat lost in the leads to the Therlo coil, we must now reduce this value by 1.5%. Thus, the final result becomes 159.5 calories per gram.

TABLE I

Heat of Vaporization of Iso-Propyl Alcohol

The individual results obtained in Series C.

Determination number	Heat of Vaporization	Determination number	Heat of Vaporization
1	159.5 cal.	5	161.5 cal.
2	161.9 "	6	161.2 "
3	161.2 "	7	161.7 "
4	160.8 "	8	161.9 "
Mean result of Series C		161.21 "	

In Table II we have summarized our experimental results for five series of determinations on iso-propyl alcohol and two series on ethyl alcohol. The data given serve to indicate the type of concordance obtained in successive series of determinations.

TABLE II
Summarized Data for the Heats of Vaporization of Iso-Propyl
Alcohol and of Ethyl Alcohol

Discussion

As shown in the preceding table, our mean result for the heat of vaporization of iso-propyl alcohol is 161.7 calories per gram at its boiling point (82.2°). Luginin and Brown in earlier investigations obtained 157.8 and 161.1 calories, respectively. Of these two values, that of Brown is undoubtedly the more trustworthy because of the relatively great care and precision of his experimental method. The recent result of Mathews, 159.23 cal. at 81.25°, appears to be the product of an extremely refined apparatus and a painstaking procedure, although from his paper it is not clear that he was able to entirely avoid the production of fog or spray in the vaporization process. Of course, such spray tends to produce results that are too low and has constituted one of the major sources of error in past calorimetric determinations of heats of vaporization. However, in the present case this may not be the cause of the discrepancy between our result and that of Mathews, for it appears that he used material that differed appreciably from ours. He reports a density of 0.7830 25°/4° for his iso-propyl alcohol and this, on the basis of our own standards of purity (essentially the density determination of Brunel¹), corresponds to a liquid containing 0.94% water. Taking all these points into consideration, we therefore would like to suggest 161.0(±1.5) calories per gram as the most likely value for the heat of vaporization of iso-propyl alcohol.

In the case of ethyl alcohol, our mean result is 208.7 calories at the boiling point, 78.4°. The more important earlier values² are 201.5 (Luginin), 205.1

¹Brunel: J. Am. Chem. Soc., 45, 1336 (1923).

²Landolt-Börnstein-Roth-Scheele: "Tabellen," 1480 (1923).

(Wirtz), 206.4 (Schall), 207.2 (Young), 216.5 (Marshall and Ramsay) and 216.4 (Brown). Mathews' recent determination gave 201.88 at 77.4°. The average of all these results, 207.9 calories, agrees very well with our own value and is about midway between those so carefully obtained by Brown and by Mathews. Hence, as a provisional value for use at the present time, 208 calories per gram is probably as satisfactory and reasonable as any other that might be suggested. However, in the case of a very common and important substance like ethyl alcohol, such a marked variation in the experimental results is extremely unfortunate; certainly the situation requires further research for its clarification.

EQUILIBRIUM IN ELECTROLYTE SOLUTIONS

BY FREDERICK GEORGE SOPER

The condition which must be satisfied by all systems in true equilibrium is that the Free Energy change occasioned by a slight displacement of the system from the equilibrium position, is zero. Application of this principle to homogeneous equilibria of the type, $A + B + \dots \rightleftharpoons P + Q + \dots$, leads to the equation

$$F_A + F_B + \dots = F_P + F_Q + \dots \quad (1)$$

where the F 's denote the partial free energies, as a definition of the equilibrium state. Whilst this equation is probably strictly true of a gaseous system, its application to equilibria in liquid media may occasionally lead to erroneous results, for a slight displacement of the equilibrium may be associated with a slight change in the partial free energy of the liquid medium. The condition of equilibrium is thus more precisely given by

$$dF_A + dF_B + \dots + dF_P + dF_Q + \dots + dF_{\text{medium}} = 0 \quad (2)$$

for a small displacement. For equilibria involving neutral molecules this change in the partial free energy of the medium may usually be ignored, but for equilibria involving ions it may under certain circumstances be considerable, as it comprises 1/3rd of the net partial free electrical energy change of the ions caused by the slight displacement of the ionic equilibrium.

In order to demonstrate this result which follows directly from the Debye-Hückel theory¹ of strong electrolytes, the determination of the activity coefficient of an ion in terms of the valence of the ion and of the ionic strength μ , will first be considered. In Debye's evaluation of the total electrical free energy of an electrolyte solution² the ions are considered as initially uncharged so that if their concentration is c the free energy of the system in the uncharged state will be $F_0 + nkT \ln c/c_0$, where F_0 is the free energy of the system at the infinitely small concentration c_0 . The electrical work required to increase the charges of the ions reversibly to their final values is evaluated as $A_e = \sum n_i z_i e \psi_i / 3$, where z_i is the number of unit charges, e , possessed by the n ions of the i 'th kind considered and ψ_i is the potential at one of these ions due to the surrounding ion atmosphere. As was shown by Debye and Hückel (*loc. cit.*), $\psi_i = -z_i e \kappa / D$, κ being a quantity characteristic of the solution and defined by

$$\kappa^2 = \frac{4\pi}{DkT} \sum n_i z_i^2 e^2 = \frac{8\pi e^2 N \mu}{10^3 DkT}$$

¹ Physik. Z., **24**, 185 (1923).

² Debye: Physik. Z., **25**, 97 (1924).

The total free energy of the electrolyte solution is thus $F_0 + nkT \ln c/c_0 - n_1 z_1^2 e^2 \kappa / 3D$, or for a symmetrical binary electrolyte forming a total number of n ions

$$F = F_0 + nkT \ln c/c_0 - nz^2 e^2 \kappa / 3D \quad (3)$$

The free energy change measured in reversible concentration cells is the free energy of transfer of ions from one solution where their concentration is c_1 to another where their concentration is c_2 , i.e., the free energy change is the *partial* free energy change of the ions. In order to compare the activity coefficients of ions deduced from these measurements of partial free energy changes, with the theory, Debye calculated the partial free energy of the electrolyte by differentiating the total free energy of the solution with respect to n and so obtained the result

$$\bar{F} = nkT \ln c/c_0 - nz^2 e^2 \kappa / 2D \quad (4)$$

Part of the electrical free energy of the electrolyte solution must therefore reside in the medium since the total free electrical energy is $-nz^2 e^2 \kappa / 3D$, whilst the partial free electrical energy of the ions is $-nz^2 e^2 \kappa / 2D$. This leaves $+nz^2 e^2 / 6D$ as the partial free electrical energy of the medium.

Comparison of the partial free energy of the ions with the expression $\bar{F} = nkT \ln f c/c_0$, which defines the activity coefficient f in terms of the solution concentration c_0 of unit activity coefficient, shows that

$$\begin{aligned} \ln f &= -nz^2 e^2 \kappa / 2DkT \\ \text{or } \log f &= -0.505 z^2 \sqrt{\mu} \text{ at } 25^\circ. \end{aligned} \quad (5)$$

Conditions of equilibrium in a balanced reaction associated with a change in the partial free electrical energy.—As a simple example of a balanced reaction in which a change in the free electrical energy occurs, an equilibrium of the type $HA \rightleftharpoons H^+ + A^+$, may be considered, where a weak acid HA ionises forming ions H^+ and A^+ . Let dn mols of HA ionise, forming dn ions each of H^+ and A^+ , and let c_{HA} , c_H , and c_A be the various equilibrium concentrations. The free energy change of the system, dF , associated with this small displacement, will be $dF_{HA} + dF_H + dF_A + dF_{\text{medium}}$, and at equilibrium $dF = 0$. Thus

$$\begin{aligned} &-dF_{HA} - \frac{dn}{N} RT \ln c_{HA} + dF_H + \frac{dn}{N} RT \ln c_H - \\ &dnz^2 e^2 \kappa / 2D + dF_A + \frac{dn}{N} RT \ln c_A - dnz^2 e^2 \kappa / 2D + 2 \times dn z^2 e^2 \kappa / 6D = 0 \end{aligned}$$

and therefore

$$\ln \frac{c_H c_A}{c_{HA}} = \text{Const.} + \frac{2z^2 e^2 \kappa}{3DkT} \quad (6)$$

For an equilibrium of the type

$$\ln \frac{c_P^{z_4} c_Q^{z_5} \dots}{c_A^{z_1} c_B^{z_2} c_C^{z_3} \dots} = \text{const.} + \frac{e^2 \kappa}{3DkT} \left(z_4^2 + z_5^2 - (z_1^2 + z_2^2 + z_3^2) \right) \quad (7)$$

The activity equilibrium constant.—The activity of a molecular species A, may be defined by the equation, $F_A = RT \ln a_A + C_A$, where a_A is the activity and C_A is a constant. This definition leads to the activity equilibrium constant if (1) is valid. As has been indicated (1) is not applicable to ionic equilibria in which a displacement of the equilibrium is attended by a change in the free electrical energy of the system. An alternative procedure is to define activities by the activity equilibrium constant and so evaluate "apparent" activity coefficients. For the ionic equilibrium $HA \rightleftharpoons H^+ + A'$, this method would give

$$\frac{a_H a_{A'}}{a_{HA}} = \frac{c_H c_{A'}}{c_{HA}} \cdot \frac{f_H f_{A'}}{f_{HA}} = \text{Const.}$$

and since f_{HA} may be regarded as unity,

$$\ln \frac{c_H c_{A'}}{c_{HA}} = \ln \text{Const.} - 2 \ln f_1 \quad (8)$$

where f_1 is the activity coefficient of a univalent ion.

Comparison of equations (6) and (8) gives

$$\ln f_1 = z^2 e^2 \kappa / 3 D k T \quad (9)$$

or $\log f = -0.33 z^2 \sqrt{\mu}$ at 25° .

A similar result is obtained by application of the ionic velocity equation (previous paper) to the equilibrium $HA \rightleftharpoons H^+ + A'$. The rate of interaction of the ions is given by

$$v = k c_H c_{A'} e^{-E_0/kT + 1.52 \sqrt{\mu}} \quad (10)$$

whilst the rate of ionisation is given

$$v' = k' c_{HA} e^{-E_0'/kT} \quad (11)$$

At equilibrium $v = v'$, and

$$\frac{c_H c_{A'}}{c_{HA}} = \left(\frac{k' e^{-E_0'/kT}}{k e^{-E_0/kT}} \right) e^{-1.52 \sqrt{\mu}}$$

$$\text{or } \log \frac{c_H c_{A'}}{c_{HA}} = \log \text{Const.} - \frac{1.52}{2.303} \sqrt{\mu} \quad (12)$$

Comparison of equation (12) with (8), gives

$$\log f_1 = -0.33 \sqrt{\mu}$$

Activity coefficients evaluated from the definition of activity in terms of the partial free energy, $F_A = C_A + RT \ln a_A$, thus correspond to a limiting law of $\log f = -0.50 z^2 \sqrt{\mu}$, whilst activity coefficients evaluated from the equilibrium constant definition, $a_A a_B \dots a_P a_Q \dots K$, correspond to the limiting law $\log f = -0.33 z^2 \sqrt{\mu}$, when the equilibrium is such that neutral molecules are in equilibrium with ions. There are consequently two series of activity values which will in general differ from each other. It may be of interest to consider briefly to which series the various measurements of activity should be assigned.

¹ Lewis: Proc. Am. Acad., 43, 259 (1907); Z. physik. Chem., 61, 129, (1907).

Activities from solubility.—Since the calculation of activity coefficients from solubility measurements is based on the condition that the ionic activity product is constant, such activity coefficients should show agreement with the formula $\log f = -0.33 z^2 \sqrt{\mu}$. This result is obtained more directly by consideration of the free energy change attending the solution of a small quantity of salt in the saturated solution, remembering that each ion formed contributes $+ze^2k/6D$ to the partial free electrical energy of the medium. Brönsted found for univalent electrolytes¹ that the limiting law, $\log f = -0.42 c^{1/2}$, satisfied the solubility relationships. Later work,² however, has been in accordance with the expression $\log f = -0.50 z^2 \sqrt{\mu}$, but since when the ionic radii are taken into account the Debye equation becomes

$$\log f = \frac{-z^2 B \sqrt{\mu}}{1 + Aa \sqrt{\mu}}$$

where A and B are constants, B having the value 0.505 or 0.33, the evaluation of B from experimental data depends on the value assigned to a , the ionic radius.

The measurement of the partial vapour pressure of the electrolyte in the solution, as in the case of the halogen acids, may be considered as a solubility method and the activity coefficients obtained by this method correspond to the limiting law, $\log f = -0.33 z^2 v$. It must therefore follow that the vapour pressure of an electrolyte is not even approximately proportional to the fugacity,³ f' , as defined by $FA = RT \ln f' + CA$.

Activities from freezing points.—In the measurement of activities from the freezing point depression one obtains primarily the activity of the solvents in the solution. At the freezing point the activity of the solvent in the solution is equal to the activity of the solid solvent and the change in both these activities with temperature is calculable. In a solution at any desired temperature the activity of the solvent present is therefore known. The partial free energies of the solvent and the solute, F^1 and F^2 respectively, are connected by the equation⁴

$$N_1 \left(\frac{\partial F^1}{\partial N_1} \right) + N_2 \left(\frac{\partial F^2}{\partial N_1} \right) = 0$$

If one defines the activity by $F_2 = RT \ln a_2 + C_2$, then

$$N_1 \left(\frac{\partial a_1}{\partial N_1} \right) + N_2 \left(\frac{\partial a_2}{\partial N_1} \right) = 0$$

and one obtains from this equation the activity of the solute corresponding to the above definition and therefore to the limiting law for the activity coefficient $\log f = -0.50 z^2 \sqrt{\mu}$.

Summary

1. The equation for the equilibrium of electrolytes in solution has been modified to take into account the partial free electrical energy of the medium as deduced from the Debye-Hückel theory of electrolytic solutions.

¹ J. Am. Chem. Soc., **44**, 938 (1922).

² Scatchard: J. Am. Chem. Soc., **47**, 641 (1925).

³ Lewis: loc. cit.

⁴ Lewis and Randall: "Thermodynamics", 207 (1923).

2. It is shown that the two definitions of activity (1) in terms of the partial free energy $F_A = RT \ln a_A + C'_A$, and (2) in terms of the equilibrium constant, $a_A a_B \dots / a_P a_Q \dots = K$, lead, when applied to electrolytes, to two series of values.

3. Activity coefficients evaluated from values for the activity of the solvent, e.g., from the freezing point depression, correspond to the Debye limiting law, $\log f = -0.50 z^2 \sqrt{\mu}$, whilst activity coefficients evaluated from solubility measurements or from the partial v. p. of the electrolyte correspond to the limiting law, $\log f = -0.33 z^2 \sqrt{\mu}$.

THE SYSTEM $\text{Na}_2\text{O} : \text{SiO}_2 : \text{H}_2\text{O}$

Relationship between Composition and Boiling Point of Aqueous Solutions of Sodium Silicate. II*

BY JESSIE Y. CANN AND KEREN E. GILMORE¹

This investigation is a continuation of the research begun by Cann and Cheek² on the relationship between composition and boiling points of the system $\text{Na}_2\text{O} : \text{SiO}_2 : \text{H}_2\text{O}$ i.e. so-called aqueous solutions of sodium silicate. Because of the peculiar characteristics of silicate solutions, no work had been recorded upon this subject prior to 1925.

Apparatus and Materials

The apparatus used for all determinations in this work was the Cottrell³ boiling point apparatus, as modified by Washburn.⁴ With this it is possible to obtain a boiling point which varies only a few thousandths of a degree for a period of an hour or longer. The apparatus was made of Pyrex glass, since Cann and Cheek found that ordinary glass would not stand the necessary heat. Two similar pieces of apparatus were placed side by side on the laboratory desk and heated by burners of identical form, fed by the same gas supply, so that there was equal exposure to any slight fluctuation of atmospheric pressure, accidental draught, variation of gas pressure, etc. Each piece of apparatus was wrapped in asbestos paper, and surrounded by a box of heavy asbestos board.⁴ In one was placed conductivity water, and in the other the silicate solution. Pieces of clean unglazed porcelain were added to each to prevent bumping. The ground-glass stoppers of the apparatus in which the silicate solution was boiled were covered with tin foil to prevent possible cementing by an unavoidable trace of the silicate solution.

The silicates used in this investigation were the commercial brands "C", "K" "E" and "S" furnished by the Philadelphia Quartz Company. The ratio of soda to silica in these brands was found to be 1:1.99, 1:2.87, 1:3.15 and 1:3.75 respectively. "E" was clear, light in weight and very mobile. "S" was very much like "E" except that it was opalescent. "K" was much darker, slightly heavier and more viscous. "C" was transparent, heavy and exceedingly viscous, and most difficult to handle. The color was probably due to traces of iron found in analyses of each. These samples were kept in block-tin containers.

Conductivity water was used throughout the investigation.

*Contribution from the Chemistry Laboratory of Smith College.

¹ The experimental work of this paper was submitted by Keren E. Gilmore in partial fulfillment of the requirement for the degree of Master of Arts at Smith College.

³ J. Am. Chem. Soc., **41**, 721 (1919).

⁴ Washburn and Read: J. Am. Chem. Soc., **41**, 729 (1919).

Experimental Work

The solutions used for the determinations were prepared by adding silicate to water with brisk stirring.² From the reputed soda content, solutions of varying approximate percentage composition were made up. Half a liter of each was prepared in order to provide sufficient material for the boiling point determinations to be made in duplicate. The solutions were then allowed to stand twenty-four hours in stoppered glass bottles, since it is a well known fact that the composition of freshly diluted silicate solutions varies during the first twelve or fifteen hours but that after this no change occurs. During the period that the dilute solutions were kept in the glass bottles no reaction took place between the solutions and the glass, for two determinations were in as close agreement when made a week apart as when made on the same day.

The volume of solution used for each determination depended upon the particular apparatus. It was found that the best results were obtained when the apparatus was about a third full, i.e. when the volume of the solution was about one hundred and fifty cubic centimeters. After the solution had been placed in one apparatus and conductivity water in the other, each was brought to boiling. When the Beckmann thermometer in each, after being gently tapped, showed, through the lens, that the readings were constant within a few thousandths of a degree, a succession of readings was recorded at two minute intervals. Immediately before and after each determination the barometric pressure and the temperature at the barometer were read. The barometer was on the same level as the apparatus. By the simultaneous use of these two pieces of apparatus any possible error caused by fluctuation in atmospheric conditions was reduced to a minimum.

Solutions made from "E" and "C" frothed badly. This frothing increased with increasing concentration. When the soda content exceeded three per cent the foam extended above the thermometer bulb, and, in some cases, completely filled the apparatus. An attempt was made to lessen the effect of the foam on the attainment of equilibrium by fastening a piece of perforated sheet platinum to the stem of the pumping apparatus about two inches above the liquid. This reduced the frothing somewhat, but did not prevent a portion of the foam from reaching the thermometer bulb.

It was impossible to determine the boiling-point elevation of silicate solutions which contained over eighteen per cent silica without injuring the apparatus. A white crystalline-like substance was deposited in the bottom of the apparatus which either softened the glass or cracked it. The Pyrex glass was easily forced out of shape by the weight of the solution. This behavior of Pyrex glass is not an unusual phenomenon. Morey⁵ attributes it to the high per cent of B_2O_3 and SiO_2 in the glass.

⁵ Private communication. "While Pyrex is a good glass to withstand acid solutions it is perhaps the poorest for alkalis. A Pyrex tube will be completely decomposed and all the B_2O_3 extracted by a few hours heating with water alone at 300°C , under which conditions most other glasses are but slightly affected. That ten per cent of B_2O_3 in Pyrex, taken in connection with eighty per cent of silica and the low content of basic oxides, makes it peculiarly susceptible to the action of strong alkalis."

The formation of this white substance is very characteristic. When the solution is first heated, a continuous stream of vapor bubbles arises from definite points on the bottom of the apparatus. As the heating continues the points grow in size and a white solid appears. The solid continues to form as long as the solution is heated. Throughout the process a large amount of water vapor separates. The greater part of the solid material goes back into solution when it is allowed to cool in contact with the supernatant liquid.

The authors separated some of this apparently crystalline material by slowly heating the stock solution of "E" in a round bottomed flask connected with a reflux condenser, and then filtering hot through a Buchner funnel. Stericker⁶ examined microscopically some of this white solid and found that it consisted of spherical shells with holes in one side from which the bubbles of water vapor arose. Morey⁷ made a more thorough microscopic study of the material. He powdered it, immersed it in a liquid of known refractive index, and tested its behavior in polarized light. All silicates are biaxial crystals and therefore show birefringence. The material examined has only one refractive index which indicates that it is a liquid and therefore belongs to the category of glasses. Morey² affirms that it is very difficult to crystallize sodium silicate from an aqueous solution. If crystallization occurs the solution has to be free from such impurities as iron oxide and alumina, and heated under definitely prescribed conditions of temperature and composition. Thus if an aqueous solution of sodium silicate is heated rapidly a glass results.

The accurate soda content of all solutions was determined by titration with standard acid, using methyl orange as an indicator. The complete analysis of the original samples was carried out according to the accepted methods of Hillebrand.⁸

Results

Sixteen determinations of the boiling-point of conductivity water at different pressures were made with both Beckmann thermometers. The observed barometric pressures were corrected to 0°C for the expansion of mercury with temperature according to Landolt and Börnstein.⁹ The boiling points¹⁰ at these corrected pressures correspond exactly to the observed Beckmann readings. The average of these Beckmann readings, corrected to 760 m. m. pressure, correspond to 100°C. The reading on the thermometer used in the silicate apparatus, corresponding to the boiling point of water under standard conditions, is 0.0963° higher than the analogous reading of the thermometer used in the water apparatus.

†Used new apparatus for water which did not pump well.

In Table I are given the boiling point elevations of the silicate solutions at 760 m.m. pressure, and the percentage soda content of the solutions. The figures in the second column represent the barometric pressure corrected to 0°C .⁹ The figures in the fifth column are obtained by adding 0.0963 to those in the fourth column. The figures in the sixth column are the differences between those in the third and the fifth. The figures in the seventh column were calculated according to Washburn and Read.¹¹

TABLE II
Analysis of Original Samples

*The high Al_2O_3 values are evidently due to traces of other elements (Ti , etc.) for which tests were not made.

Table II gives the complete analyses of the original silicate solutions, and Table III gives the complete analyses and calculated formulas of all the solutions of "C", "K", "E" and "S" that were used.

¹¹ J. Am. Chem. Soc., **41**, 738 (1919).

It will be noticed that in calculating the formulas, the percentages of the impurities—i.e. Fe_2O_3 , Al_2O_3 , CaO and MgO —are ignored. This has been done because it is believed that these percentages are so small as to be negligible.

In Table IV are given the activity coefficients of all the solutions whose boiling points were determined. These values were calculated according to the equations for concentrated solutions given by Lewis and Randall.¹² First, the molality i.e. the grams of $(\text{Na}_2\text{O})_1 (\text{SiO}_2)_x$ in 1000 grams of water was calculated for each. These values are listed in the second column. Then the

values of $j = 1 - \frac{\theta}{\nu \lambda m}$ where θ = the elevation of the boiling point, ν the

number of ions at infinite dilution, λ the molecular elevation of water i.e. 0.518 and m the molality, were calculated. These values are given in the fourth column. The value of ν was assumed to be 4, because it was desired to compare the results obtained from boiling point elevation with those obtained by Harman¹³ in all of his recently published work on silicates. Especially was it desired to compare the present results with those obtained by Harman by the freezing-point method.¹⁴ He used the value of 4 for ν to represent the four ions 2Na^+ , SiO_3^- , OH^- . Moreover it is stated by Lewis and Randall¹⁵ that it is possible to use the same equations for boiling point elevation as for freezing point depression.

Log j was next plotted against log m and the intercept (log β) on the log j axis was determined, and the slope of the line, α . From these two values

the $\int_0^{0.01} -j \, d \log m$ was obtained from equation⁵ 15, namely $\int_0^{0.01} -j \, d \log m = -\frac{\beta}{2.303\alpha} (0.01)^\alpha$. This gives the area from infinite dilution up to molality =

0.01. Then j was plotted against log m , and the curves extrapolated until they cut the axis log $m = -2$. To obtain the values of the activity coefficients

according to the equation $\log \gamma = \int_0^m -j \, d \log m - \frac{j}{2.303} + \frac{0.00025}{\nu} \int_0^m \frac{\theta}{m} \, d\theta$

given by Lewis and Randall, it is necessary, in order to determine the values

of $\int_0^m -j \, d \log m$, to obtain the area under the curve of j against log m . To

the areas, corresponding to each molality, counted to the right of the point where log $m = -2$, must be added the value of the area corresponding to

$\int_0^{0.01} -j \, d \log m$ obtained from equation 15. These values are listed in the

sixth column of Table IV.

The value of $\frac{0.00025}{\nu} \int_0^m \frac{\theta}{m} \, d\theta$ was determined for solutions of "K" only,

because its value was found to be entirely negligible.

Table V is a summation of all the results showing the activity coefficients of all the ratios for the same molalities.

Discussion of Results

The results of this investigation are, for the most part, in agreement with those of Harman.¹³ The curves in Fig. 1 show that concentrated solutions have proportionately less effect on the boiling point elevation than dilute solutions i.e. as concentration increases the percentage elevation in boiling point decreases. It is therefore believed that the degree of dissociation of solute decreases as concentration increases. Since the curves of "BW" (1:1.68) and "C" (1:1.99) have the greatest slope, it is evident that concentrated solutions which have a relatively small percentage of silica produce the greatest effect on the boiling point. For this reason the degree of dissociation is believed to be greater in solutions in which the ratio of soda to silica is low. It will be noticed that the slope of "S" (1:3.753) is different from that of any other curve. The boiling point elevation is exceptionally high in the dilute solutions and abnormally low in the concentrated solutions. Harman observed an analogous result from the freezing point depression of the 1:4 ratio. He attributes this result to micelle formation, which undoubtedly exists in this ratio.¹⁷

The curves in Fig. 2 for "BW" (1:1.68), "Star" (1:2.55), "K" (1:2.874) and "S" (1:3.753) agree with the foregoing statements. It will be noticed that "E" (1:3.154) and "C'" (1:1.995) do not agree entirely with these statements. It will be recalled that solutions of "E" and "C" gave trouble because of frothing and so-called crystal formation.

It will also be noticed that in "C", only, have the three *negative* values of j been included. Two *negative* values of j for "K" and two for "S" have been omitted. The reason for this is that the omitted values for "K" and "S" were considered unreliable because of the extreme dilution. This was not considered true of the "C'" values; although, if these three values for "C" in extremely dilute solution were discarded, the results would be more nearly concordant. Moreover, according to LaMer,¹⁸ from a thorough study of the best data in the literature, very slight experimental errors render j almost indeterminate in very dilute solutions. There is also the possibility that ν may not be equal to 4 in these dilutions. La Mer¹⁸ states "the silicate complexes in "C", dissociating as a weak electrolyte at the very high dilutions, may give more ions."

It had been thought that a decided change might take place in the composition of silicate solutions on prolonged heating. But results obtained by plotting time against elevation of boiling point, taken at two minute intervals, indicated no appreciable change during boiling.

Summary

1. The boiling point elevations of sodium silicate solutions of ratios 1:1.995, 1:2.874, 1:3.154 and 1:3.753 at various concentrations have been measured.
2. The values of the boiling point elevations have been plotted against the molalities.
3. The values of the activity coefficients have been calculated and plotted against the molalities.
4. The results of Cann and Check on ratios 1:1.68 and 1:2.55 have been treated similarly and added for comparison.
5. The results show that the degree of dissociation of solute decreases as concentration increases.
6. The boiling point elevations of dilute solutions of the ratio 1:3.753 are abnormally high while the elevations of the concentrated solutions are abnormally low, thus indicating micelle formation in this ratio.

A STUDY OF THE ACTIVITY AND FREE ENERGY OF DILUTION OF SOME SALTS OF CADMIUM

BY FREDERICK H. GETMAN

Although the activity coefficients of many typical electrolytes in both dilute and concentrated aqueous solutions have been determined, relatively few measurements have been recorded for the salts of cadmium. Apparently the only reliable data on the activity of cadmium salts are to be found in the experimental work of Horsch¹ on solutions of cadmium chloride and in the tables of activity coefficients of electrolytes compiled by Lewis and Randall.²

Owing to the fact that all of the salts of cadmium are somewhat anomalous in their behavior as electrolytes, it is highly desirable that their activity coefficients should be determined. With a view to supplying this data, the experimental work recorded in the present paper was undertaken. The salts which have thus far been studied are the chloride, bromide and sulphate of cadmium. Subsequently we hope to publish the results of studies now in progress on the activity of cadmium iodide.

Materials and Solutions

Cadmium Chloride. Chemically pure cadmium chloride was recrystallized, first from pure distilled water, and then from conductivity water. A determination of the water of crystallization in a sample of the dry salt showed it to contain 19.77% of water, while the theoretical content of water in $\text{CdCl}_2 \cdot 2\frac{1}{2} \text{H}_2\text{O}$ is 19.72%.

Cadmium Bromide. A sample of chemically pure cadmium bromide was subjected to a similar process of recrystallization, but no attempt was made to confirm its purity by analysis.

Cadmium Sulphate. Chemically pure cadmium sulphate, $\text{CdSO}_4 \cdot \frac{8}{3} \text{H}_2\text{O}$, suitable for the preparation of Weston cells, was subjected to a single recrystallization before using.

Mercury and Mercury Salts. All of the mercury used for electrodes, or for the preparation of amalgams, was of a very high order of purity, having been supplied through the courtesy of the Eppley Laboratories. Through the kindness of the same organization, samples of both electrolytic mercurous chloride and mercurous sulphate were obtained. The mercurous bromide which served as a depolarizer in the cadmium bromide cells was obtained from Kahlbaum and was certified to be chemically pure. Before setting up the bromide cells, the mercurous bromide used was shaken with the electrolyte in the presence of several globules of pure mercury.

Precautions were taken to protect all of the mercury salts from the action of light, both before and after assembling the cells.

¹ Horsch: J. Am. Chem. Soc., 41, 1787 (1919).

² Lewis and Randall: "Thermodynamics," 344, 362 (1923).

Cadmium. The cadmium employed in the preparation of the amalgams was also obtained from Kahlbaum and was guaranteed to be of a high order of purity. A stick of this metal also served as the anode of an electrolytic cell in which crystalline cadmium was deposited on spirals of platinum wire which subsequently were employed as negative electrodes in the experimental cells.

Solutions. All solutions were prepared with conductivity water. The concentrations of the stock solutions were determined gravimetrically, the chlorides and bromides being weighed as the corresponding silver halides and the sulphates as barium sulphate. The densities of the stock solutions were employed to express all concentrations in mols per 1000 grams of solvent.

Amalgams. All of the amalgams were prepared by direct weighing and contained 10% of cadmium. In the preparation of the amalgams the usual precautions were observed to prevent oxidation.

Apparatus

The measurements of electromotive force were carried out with a Leeds and Northrup Type K potentiometer in conjunction with a Type R galvanometer of high sensitivity manufactured by the same concern. Two independent standards of reference were employed, viz., (1) a Weston standard cell the electromotive force of which had recently been certified by the U. S. Bureau of Standards to be 1.01816 volts at 25.5 °C, and (2) an Eppley standard cell of the unsaturated Weston type the electromotive force of which was certified by the maker to be 1.01896 volt at 20°C. The cells were immersed in an electrically heated and controlled bath maintained at 25°C. and regulated to 0.01°. Temperatures were read on a thermometer which had been compared with a laboratory standard thermometer. The cells employed were either of the familiar H-form, or were made from large test-tubes provided with suitable sealed-in platinum connections.

Experimental

The following cells have been studied in this investigation:

- (1) $\text{Cd} - \text{CdCl}_2(\text{M}) - \text{Hg}_2\text{Cl}_2 - \text{Hg}$,
- (2) $\text{Cd} - \text{CdBr}_2(\text{M}) - \text{Hg}_2\text{Br}_2 - \text{Hg}$,
- and (3) $\text{Cd} - \text{CdSO}_4(\text{M}) - \text{Hg}_2\text{SO}_4 - \text{Hg}$.

The cadmium electrodes consisted either of 10% cadmium amalgams, or of pure electrolytic cadmium deposited on spirals of platinum wire from a solution of chemically pure cadmium sulphate to which a few drops of concentrated sulphuric acid had been added. A current of one milliampere was allowed to flow through the cell for two hours, thus insuring a deposit of approximately four milligrams of crystalline cadmium. Cadmium electrodes prepared in this manner, on immersion in a solution of a cadmium salt at 25°C., have been found¹ gradually to acquire a potential corresponding to that of the modification of the metal known as α -cadmium which Cohen

¹ Getman: J. Am. Chem. Soc., 39, 1806 (1917).

and others¹ have shown to be stable at ordinary temperatures. The average value of the electromotive force of a 10% cadmium amalgam against pure α -cadmium at 25° was found to be 0.04742 volt, thus confirming the results of the earlier investigations to which reference has just been made. The electromotive forces of all cells in which the negative electrodes consisted of 10% cadmium amalgams were therefore increased by 0.04742 volt in order to obtain the value of the electromotive force referred to the pure metal.

In Tables I-III are given the measured values of the electromotive forces of cells in which the electrolytes were the chloride, bromide and sulphate of cadmium respectively.

FIG. 1

The data of the foregoing tables is represented graphically in Fig. 1. The four points on the curve for cadmium chloride which are designated by filled-in circles correspond to the saturated and nearly saturated solutions of the salt, and represent the experimental data obtained by Lipscomb and Hulett¹ in their studies of the calomel cell.

Similarly, the value for the electromotive force of the cell containing the saturated solution of cadmium bromide, and also designated by a filled-in circle, represents the results of Oeholm's² investigation of cadmium bromide

¹ Lipscomb and Hulett: J. Am. Chem. Soc., 38, 20 (1916).

² Oeholm: Chem. Zentr., 1, 1853 (1913).

cells. The data obtained by Horsch¹ with cells set up according to the scheme,

are reproduced in Fig. 1 for the sake of comparison with the data presented for cells in which mercury-mercurous chloride electrodes replace the silver-silver chloride electrodes employed by Horsch.

The values of the electromotive force of each of the cells tabulated above represent the average of a number of measurements extending over periods of time ranging from two to four days according to the stability of the cells. Precautions were taken to insure agreement of the individual electrodes amongst themselves; all cells which exhibited signs of instability were excluded.

With increasing dilution of the electrolytes, the electromotive force of the cells tended to fall off rapidly with time. This was especially noticeable in the cadmium sulphate cells where mercurous sulphate was used as a depolarizer. This behavior is probably due in part to increasing solubility of the depolarizer as the electrolyte becomes more dilute, and in the case of mercurous sulphate, is undoubtedly to be ascribed to the formation of a yellow basic mercurous sulphate which, according to Gouy² has the formula,

Evidence of the formation of this salt was obtained during the washing of the mercurous sulphate with the cell electrolyte in order to free the former from the sulphuric acid under which it was preserved. With all solutions of cadmium sulphate under 0.01 molal a distinct yellow coloration was observed on the surface of the depolarizer after several washings, the phenomenon becoming more pronounced as the electrolyte was diluted.

Before we can proceed to the calculation of the activity coefficients of the three salts, it is necessary to determine the potentials of the three positive electrodes in terms of the hydrogen electrode.

According to Lewis, Brighton and Sebastian³ the electromotive force of the cell,

is 0.5105 volt at 25°C. Taking the activity coefficient of HCl (0.01M) as 0.924, we have

$$\begin{aligned} E^\circ &= 0.5105 + 0.05915 \log (0.01 \times 0.924), \\ \text{or } E^\circ &= 0.2702 \text{ volt.} \end{aligned}$$

The electromotive force of the Hg-Hg₂Br₂ electrode referred to the hydrogen electrode has recently been determined by Gerke and Geddes⁴. The electromotive force of the cell,

¹ Horsch: loc. cit.

² Gouy: Compt. rend., 130, 1400 (1900).

³ Lewis, Brighton and Sebastian: J. Chem. Soc., 39, 2257 (1917).

⁴ Gerke and Geddes: J. Phys. Chem., 31, 886 (1927).

was found to be 0.2685 volt at 25°C. The activity coefficient of HBr (0.1M) may be taken as 0.814, hence

$$E^{\circ} = 0.2685 + 0.1183 \log (0.1 \times 0.814),$$

or $E^{\circ} = 0.1396$ volt.

In like manner, the Hg-Hg₂SO₄ electrode has been thoroughly investigated by both Lewis and Lacy¹ and Randall and Cushman.²

The electromotive force of the cell,

as determined by the above authors is 0.7444 volt at 25°C.

Taking 0.394 as the value of the activity coefficient of H₂SO₄ (0.0596M) we have

$$E^{\circ} = 0.7544 + 0.08873 \log (1.588 \times 0.506 \times 0.394),$$

or $E^{\circ} = 0.6213$ volt.

Calculation of the Activity Coefficients

In computing the values of the activity coefficients of solutions of the bi-univalent electrolytes, CdCl₂ and CdBr₂ we make use of the equation,

$$E = E^{\circ} - \frac{RT}{NF} \ln (4 m^3 \gamma^3),$$

while in calculating the activity coefficients of solutions of CdSO₄, we employ the corresponding equation for bi-bivalent electrolytes, viz.,

$$E = E^{\circ} - \frac{RT}{NF} \ln (M\gamma).$$

TABLE IV
Activity Coefficients of Solutions of Cadmium Chloride

<i>m</i>	<i>E'</i>	<i>E</i>	<i>γ</i>	<i>γ</i> (L & R)	<i>α</i> (18°)

Accepting as the normal electrode potential of cadmium at 25°C, $E^\circ = 0.3976$, the value determined by Horsch,¹ the above equations become, on passing to common logarithms,

$$E = E^\circ - 0.08873 \log (1.588 m\gamma),$$

and

$$E = E^\circ - 0.5915 \log (m\gamma).$$

The values of the activity coefficients given in Tables IV-VI have been calculated by substituting the smoothed values of the electromotive force, as read from the curves in Fig. 1, (referred to the hydrogen electrode) in the foregoing equations and solving for γ .

In the foregoing tables E' denotes the smoothed values of electromotive force of the cells as read directly from the curves, while E denotes the electromotive force referred to the hydrogen electrode. In the fifth column of Table IV are given the activity coefficients of solutions of cadmium chloride as computed by Lewis and Randall² from the measurements of Horsch. In the sixth

¹ Horsch, loc. cit.

² Lewis and Randall: "Thermodynamics," 362 (1923).

column of Table IV and in the fifth columns of Tables V and VI are given the corresponding values of the conductance ratio, α , at 18°C., as computed by Noyes and Falk.¹ The sixth columns of Tables V and VI contain approximate values of the activity coefficients, estimated in the following manner:

$$\alpha_{\text{CdCl}_2} : \alpha_{\text{CdBr}_2} \text{ (or } \alpha_{\text{CdSO}_4}) = \gamma_{\text{CdCl}_2} \text{ (from Table I)} : \gamma_{\text{CdBr}_2} \text{ (or } \gamma_{\text{CdSO}_4})$$

FIG. 2

The curves of Fig. 2 are plotted from the data of Tables IV-VI, and represent the activity coefficients as a function of the logarithm of the concentration. Owing to the ease with which mercurous sulphate forms a basic salt in the more dilute solutions of cadmium sulphate, no attempt has been made to calculate the activity coefficients for cadmium sulphate at concentrations below 0.05 molal. It was this unsatisfactory behavior of mercurous sulphate in dilute solutions which led Horsch² and others to abandon its use as a depolarizer.

Free Energy of Dilution

From the data recorded in the above tables it is possible to compute the free energy of dilution accompanying ten-fold changes in concentration in the solutions of each of the three electrolytes. Thus, if we have two cells

and

the free energy of dilution, ΔF , accompanying the change from concentration M_1 to concentration M_2 is given by the formula

$$\Delta F = \frac{2 \times \Delta E \times 96500}{4.182},$$

¹ Noyes and Falk: J. Am. Chem. Soc., **34**, 475 (1912).

² Horsch: loc. cit.

where ΔE is the difference in electromotive force of the two cells, 4.182 is the electrical equivalent of heat and 96500 coulombs is the faraday equivalent. The data of the subjoined tables have been computed in this manner.

Thermochemical Data

As is well known, the thermal change accompanying a chemical reaction can be readily calculated from the measured values, at several different temperatures, of the electromotive force of a cell in which the particular reaction takes place. Thus, on substituting in the Gibbs-Helmholtz equation,

$$Q = 0.2389 NF \left(E + T \frac{dE}{dT} \right),$$

the observed value of E , at temperature T , and the value of dE/dT , derived from the observed variation of E with T , we can calculate the value of Q , the heat of the cell reaction at temperature, T .

In this manner, Lipscomb and Hulett¹ computed the heat of the reaction,

to be 30,060 cal. from measurements of the electromotive force of the cell,

Since the heat of the reaction is numerically equal to the difference between the heats of formation of the two salts, CdCl_2 and Hg_2Cl_2 , it follows that if the heat of formation of the latter is known, the heat of formation of CdCl_2 can be calculated. After making due allowance for the heat of hydration of the cadmium salt, the heat of formation of CdCl_2 , as calculated from Lipscomb and Hulett's data, is found to be 93,710 cal. The value for the heat of formation of this salt according to Thomsen² is 93,240 cal.

In like manner we have computed the heat of formation of CdBr_2 from measurements of the electromotive force of the cell,

at 15.5°, 18.7° and 25°. The value of E_{298° was found to be 0.60506 volt and $dE/dT = 0.000163$. Hence, on substituting in the Gibbs-Helmholtz equation, we have

$$\begin{aligned} Q &= 2 \times 96500 \times 0.2389 (0.60506 - 298 \times 0.000163), \\ &= 25,659 \text{ cal.} \end{aligned}$$

The values of the heat of formation of Hg_2Br_2 recorded in Landolt and Boernstein's tables are as follows: 49,000 cal. (Nernst) and 49,200 cal. (Varet). Taking 49,100 cal. as the probable value of the heat of formation of Hg_2Br_2 , it follows that the heat of formation of CdBr_2 is 74,759 cal. This is in close agreement with the value found in a similar manner by Oblata³ viz., 74,700 cal.

No attempt was made to determine the temperature coefficient of cadmium sulphate cells since this has been measured repeatedly in connection with the numerous studies which have been made of both saturated and unsaturated Weston cells.

Discussion of Results

The measured values of electromotive force recorded in Tables I-III when plotted against the logarithm of the corresponding concentration, as in Fig. 1, are found to lie on smooth curves and to show relatively little deviation, except in the most dilute solutions. At high dilutions, however, not only does the increasing solubility of the depolarizer tend to lower the electromotive force of the cells, but errors whose origin is more or less obscure become accentuated as the concentration is diminished. In the more concentrated solutions, it is believed that the values of the electromotive force are accurate to within a few tenths of a millivolt, while in the most dilute solutions the estimated error rarely exceeds 0.001 volt. The errors in the values of the activity coefficients derived from these measurements are like-

¹ Lipscomb and Hulett: loc. cit.

² Thomsen: "Thermochemische Untersuchungen," 3, 201 (1883).

³ Oblata: Proc. Phys. Math. Soc. Japan, (3) 3, 64 (1921).

wise greatest in the most dilute solutions, but in no case is it believed that the error exceeds one percent. The values of γ given in the fourth and fifth columns of Table IV show satisfactory agreement in the more concentrated solutions with the experimental data of Horsch.

The approximate values of γ for solutions of cadmium bromide, estimated from their conductance ratios, and the corresponding conductance ratios and activity coefficients of cadmium chloride show remarkable agreement.

FIG. 3

Similar estimated values of γ given in the sixth column of Table VI show less satisfactory agreement. This is not surprising, however, since the manner of dissociation of cadmium sulphate is not strictly comparable with that of the chloride. The values of the activity coefficients of solutions of the cadmium halides apparently differ more widely from each other than do the activity coefficients of solutions of the alkali halides.

Lewis and Randall¹ have derived an equation by means of which the activity coefficient of a solution can be calculated from its freezing point provided the latter is known with accuracy. If we neglect the heat of dilution of the electrolyte, the equation takes the form,

¹ Lewis and Randall: "Thermodynamics," 347 (1923); Lewis and Linhart: J. Am. Chem. Soc., 41, 1952 (1919).

$$\log \gamma = \int_0^m -j \, d \log m - \frac{j}{2.303} + \frac{0.00025}{\nu} \int_0^m \frac{\theta}{m} \, d \theta,$$

where

$$j = 1 - \frac{\theta}{\nu \lambda m},$$

θ being the freezing point depression of the solvent, ν the number of ions into which the electrolyte dissociates, $\lambda = 1.858$ and m the molality of the solution. On applying this equation to the best available freezing point data, Lewis and Randall¹ computed the activity coefficients of solutions of cadmium sulphate at different concentrations. The data thus obtained, together with the values of γ given in Table VI, are represented graphically in Fig. 3. The results based upon freezing point data are represented by crosses and dotted curves, whereas the values derived from electromotive force measurements are represented by circles and full-line curves. It will be noted that the two curves are not coincident, and that the activity coefficients at 25°C. change more rapidly with concentration than do the activity coefficients of the same solution in the neighborhood of 0°C. Owing to the well-known tendency of cadmium salts to form complexes in solution this behavior is not altogether surprising.

A computation similar to that of Lewis and Randall has been made for solutions of cadmium chloride. Owing to the lack of thoroughly reliable freezing point data for this salt no claim is made for the accuracy of the results, but inspection of Fig. 3, in which the computed values of γ are plotted, reveals a marked similarity between the curves representing the values of γ for solutions of cadmium chloride, as derived from freezing point and electromotive force data respectively, and the corresponding curves for solutions of cadmium sulphate.

Summary of Results

(1) The following cells have been studied:

- (1) $\text{Cd} - \text{CdCl}_2(\text{M}) - \text{Hg}_2\text{Cl}_2 - \text{Hg},$
- (2) $\text{Cd} - \text{CdBr}_2(\text{M}) - \text{Hg}_2\text{Br}_2 - \text{Hg},$
- (3) $\text{Cd} - \text{CdSO}_4(\text{M}) - \text{Hg}_2\text{SO}_4 - \text{Hg}.$

(2) From the values of the electromotive forces, at 25°C., the activity coefficients of the chloride, bromide and sulphate of cadmium at concentrations ranging from 0.001M to saturation have been calculated.

(3) The values of the activity coefficients thus obtained have been compared with the corresponding values of the activity coefficients of the same salts as estimated from both conductivity and freezing point data.

(4) The free energy of dilution attending the transfer of one mol of each of the foregoing cadmium salts from concentration M_1 to concentration M_2 has been computed.

(5) The heats of formation of the chloride and bromide of cadmium have been calculated by means of the Gibbs-Helmholtz equation from the heats of the respective cell reactions.

SOME PHYSICO-CHEMICAL PROPERTIES OF STANNOUS OXIDE

BY COLIN G. FINK¹ AND C. L. MANTELL²

This work was originally done in connection with a physico-chemical study of the reduction of tin oxides by reducing gases.³ Very little accurate data in reference to stannous oxide exists in the literature. Stannous oxide is a blue-black, iridescent, crystalline substance. It is reduced by some reducing agents. On the other hand, even mild oxidizing agents readily oxidize it to stannic oxide or metastannic acid. It is easily soluble in non-oxidizing mineral acids and in a number of organic acids to form the corresponding stannous salt. Stannous oxide is ordinarily considered as a reducing agent.

Preparation of Pure Stannous Oxide

Various experimenters have failed in attempting to get pure stannous oxide, using stannous chloride as a source, treating with soda, forming the hydroxide, heating the same, filtering and washing. Sufficient oxidation or hydration took place during these procedures so that a heavy precipitate of stannic oxide was formed.

Ditte⁴ gives the following rapid method which he claims is perfectly satisfactory for the preparation of pure stannous oxide. Stannous chloride is dissolved in water and treated while hot with the smallest amount of concentrated hydrochloric acid necessary to clear the solution. The stannous hydroxide is then precipitated by the addition of a soda solution (e. g. a carbonate) which is added in small amounts until the mixture is just alkaline to phenolphthalein but not to litmus, which is too alkaline. The milk-white solution is then kept at 110° C. for several hours. After two to three hours the white material changes to a blue-black substance, stannous oxide, with its characteristic metallic sheen. The material is then washed by decantation, dried, and made ready for use.

Fraenkel and Snipischsky⁵ repeated Ditte's method successfully. Numerous methods are proposed in the literature for SnO preparation but practically all of them, except Ditte's, produce contaminated products.

Following the method of Ditte, stannous oxide was prepared from pure, c.p. stannous chloride crystals. The strict adherence to his directions as to control of alkalinity is the most important factor in the production of pure SnO. Solutions too highly alkaline (greater than pH 7) cannot be made to yield stannous oxide even after several hours boiling. Within the range of pH 5

¹ Head, Division of Electrochemistry, Columbia University.

³ Fink and Mantell: Trans. Am. Electrochem. Soc., 51.

⁴ Pogg. Ann., 27, 145 (1882).

⁵ Z. anorg. Chem., 125, 235 (1922).

to about pH 6.5, stannous oxide can be readily produced. The product, after filtration, careful washing with distilled water to free the precipitates from chlorides, and careful drying at 110° C. is blue-black, lustrous, somewhat iridescent and decidedly crystalline. Our material corresponded exactly to SnO shown by chemical analysis for Sn by iodine titration.

SnO boiled in distilled water for half an hour did not produce any stannous hydroxide or metastannic acid as could be determined by visual examination. It did not change in color, appearance, or crystalline form, in any manner observable under the microscope.

It would, therefore, seem that the reaction:

is not readily reversible. The thermal data

show it to be endothermic.

The Thermal Decomposition of Stannous Oxide

The physico-chemical properties of stannous oxide are important as they are the key of the explanation of the manner in which stannic oxide was reduced by a reducing gas.¹ The reduction of stannic oxide may be assumed to take place in either of two ways. The stannic oxide may either be reduced directly to tin metal or it may be first reduced to stannous oxide (SnO) which may be further reduced to tin metal.

The stannous oxide used was of the c.p. analyzed grade furnished by J. T. Baker Chemical Company. Chemical analysis for Sn by iodine titration showed it to be very pure as it corresponded almost exactly to the theoretical Sn percentage on a dry basis for SnO.

The literature records observations that stannous oxide is unstable above certain temperatures and therefore does not exist above this point. It is obvious that above the thermal decomposition point of stannous oxide, the reduction of stannic oxide results in the direct production of tin metal; below this point, stannous oxide may be produced.

It was desired to determine the thermal decomposition point of stannous oxide. It is readily understood that no easy chemical method exists for the separation of tin metal and stannous oxide because of their solubilities in the same reagents. It was thought that the qualitative detection of decomposition could be made by the observation of the formation of white stannic oxide. The reaction is assumed to be:

There is the objection that it is not possible, except with the most exacting care of all details, to maintain an inert gas atmosphere with a complete absence of oxygen or moisture. Both oxygen and moisture react with black stannous oxide to form the white stannic oxide. If, however, the stannic

¹ Fink and Mantell: loc. cit.

oxide formation is disregarded and only the formation of metallic tin is used as a criterion of thermal decomposition, we have a reliable method for detection of the phenomenon.

Microscopic examination by us of stannous oxide shows it to be crystalline, of the regular system, brownish black to jet black, somewhat iridescent and sparkling. The crystalline structure of finely divided or gaseous reduced tin is not observable under the ordinary microscope. It is grayish black in color. Due to its fluidity above the melting point tin forms metallic-appearing globules. The change from crystalline stannous oxide to metallic tin is easily recognized microscopically.

The apparatus set up is shown in the attached sketch. Heating of stannous oxide was done in RR alundum combustion boats in a silica tube, in an electric furnace whose current and consequent temperature was controlled by an outside resistance in series with the furnace. Temperatures were taken with a chromel-alumel (#22 gauge wire) thermocouple and a sensitive calibrated Hoskins high-resistance millivoltmeter type indicator. Heating of the SnO was done in an atmosphere of nitrogen, purified of oxygen through passage over copper wire gauze heated to 250° – 300°C . in a silica tube in an electric furnace, and freed of moisture by passage through soda lime and phosphorus pentoxide. The entire system was closed and under a slight nitrogen pressure. Excess nitrogen escaped through a mercury seal at the end of the apparatus train. Between runs any copper of the gauze which had been oxidized to copper oxide was reduced by hydrogen in preparation for the next run. Any residual hydrogen was washed out by nitrogen before the run was started. The experimental results are given in Table I. Each run has been duplicated or triplicated and checked in this way.

TABLE I
Stannous Oxide Decomposition

Temperature range	Time	Observation
610° – 620°C .	30 minutes	Metallic tin produced
530° – 540°C .	30 "	Metallic tin produced
490° – 500°C .	35 "	Metallic tin produced
440° – 450°C .	60 "	Metallic tin produced
420° – 430°C .	35 "	Metallic tin produced
400° – 420°C .	35 " "	Metallic tin produced
395° – 400°C .	30 "	Metallic tin produced
390° – 395°C .	40 "	Metallic tin produced
375° – 385°C .	60 "	No metallic tin produced
340° – 360°C .	70 "	No metallic tin produced

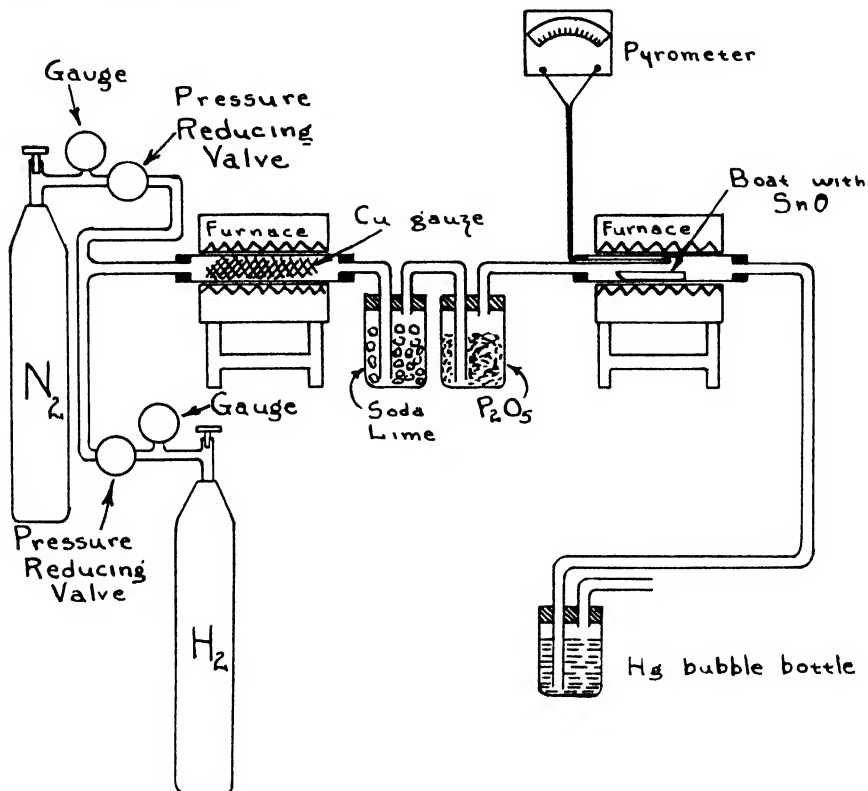

Stannous oxide is therefor thermally decomposable above 385°C . and is thermally stable below this point.

Temperatures taken with a chromel-alumel couple and high-resistance millivoltmeter. Instrument, leads, and couples were calibrated together.

It is interesting to note that Ditte¹ found that at high temperatures SnO is unstable and decomposed according to the reaction:

Fraenkel and Snipischsky² confirmed this and found that stannous oxide was unstable above 500° C.

Set-up for Determination of SnO Decomposition

FIG. 1

Our work shows that the above observations were correct but that the reaction takes place at much lower temperatures. It has been shown that stannous oxide is thermally decomposable above 385°-390° C. and is thermally stable below this point.

The reaction $\text{SnO}_2 + \text{H}_2$ can therefore not be assumed to be a two-step process of reduction above this temperature. Above 385° C. we then have the reaction:

¹ Pogg. Ann., 27, 145 (1882).

² Z. anorg. Chem., 125, 235 (1922).

perhaps interpreted as the summation reaction of:

There is considerable doubt whether the reaction proceeds as described with the reduction of SnO_2 to SnO with very rapid decomposition of the SnO to form Sn and SnO_2 .

Below the thermal decomposition point of SnO , the reduction of stannic oxide by hydrogen takes place in two stages: \

each of which can be observed. The temperature at which reduction takes place can be regulated so as to allow the formation of SnO . We have proved this point repeatedly by experiment.

As additional data for the interpretation of the means of reduction of stannic oxide, the oxidation of stannous oxide was investigated.

The Oxidation of Stannous Oxide

Compressed air was used as an oxidizing material. The air was reduced in pressure to such a value that it passed through the apparatus train at the rate of about five liters per hour. The air was washed by bubbling through two water wash-bottles in series. It was saturated with moisture at the same time. The air was cleaned of dust particles, dirt, etc. by passage through two wash bottles in series, one filled with glass wool and the other with absorbent cotton. It then entered the silica furnace tube, which was heated by an electrical resistance furnace. The stannous oxide was held in white RR aluminum combustion boats. Temperatures were taken at the center of the furnace (which was also the center of the combustion boat when it was in place in the furnace) by a calibrated chromel-alumel thermocouple and a high resistance indicator and leads.

The furnace was first brought up to the desired temperature, then opened, the boat of stannous oxide put in place and the furnace closed. The boat came to temperature very rapidly and the surface of the charge almost immediately. The boat and charge were then removed from the furnace, allowed to cool in a desiccator and then examined.

The criterion of oxidation was the formation of stannic oxide as determined by visual and microscopic examination. The color change when judged by comparison with a boat of unheated stannous oxide was readily observable, as stannic oxide is white and stannous oxide is black. Secondary confirmation was obtained by the insolubility of stannic oxide in dilute hydrochloric acid, in which the stannous oxide is completely soluble.

The data and results are given in Table II. Above 235°C . stannous oxide is instantaneously oxidizable in moist air. It burns like tinder and is almost pyrophoric in its action.

Three runs were made, at 225°C ., 230°C . and 235°C . over measured time intervals to determine whether the stannous oxide was affected over an appreciable time interval. These results are also tabulated and show that at 225°C . stannous oxide is not affected by moist air after a ten minute period. It is, therefore, concluded that from 225°C . to 235°C . stannous oxide is oxidized at a slower rate than above 235°C . Below 225°C . it is not readily oxidized by moist air.

TABLE II
SnO Oxidation

Instantaneous Temperature		Observation
410°C .		White stannic oxide produced, oxidation
360°C .		" " " " oxidation
325°C .		" " " " oxidation
300°C .		" " " " oxidation
275°C .		" " " " oxidation
250°C .		" " " " oxidation
240°C .		" " " " oxidation
235°C .		No white stannic oxide produced, therefore no oxidation.
Temperature	Time	Observation
230°C .	5 minutes	No white stannic oxide produced, therefore no oxidation.
225°C .	10 "	No white stannic oxide produced, therefore no oxidation
235°C .	10 "	No appreciable oxidation, very small amount of stannic oxide produced

Air, saturated with moisture, was blown through the tube in which the stannous oxide was heated. Material after experiment examined macroscopically and microscopically.

Temperatures taken with a Chromel-Alumel couple and high resistance voltmeter. Instrument, leads and couple were calibrated together against a standard platinum-platinum rhodium couple and precision potentiometer.

Duplicate determinations were made at the same temperatures, substituting dried air for the moist air. The air supply was the same as in the experiments but the air was cleaned and dried by bubbling through a wash-bottle of concentrated sulphuric acid, a tower packed with glass wool and absorbent cotton in alternate layers, and two soda lime towers in series. The results were quite analogous to those of moist air. Dry air effected oxidation at temperatures as low as 220°C . but not as low as 210°C . after ten minutes exposure to the warm air.

It is concluded that above 240°C . stannous oxide is readily changed to stannic oxide by both dry and moist air. At this and higher temperatures stannous oxide has pyrophoric tendencies, which increase with rise of temperature.

Oxidation of Stannous Oxide by Sulphur Dioxide in Solution

In the course of some work on the leaching of tin ores, sulphur dioxide in saturated solution was used as an aid in experimental leaching as an addition to other materials being used. Paralleling these experiments stannous oxide was leached with the same solutions. It was noticed that often the black stannous oxide was changed to a white or cream colored precipitate having the physical appearance and chemical characteristics of metastannic acid or stannic oxide. This would be in accordance with the reaction:

or

In other cases it was noticed that tin metal in finely divided form resulted from the action of SO_2 on stannous oxide very likely according to the reaction:

It is barely possible that the following reaction might occur and produce sulphur, but no metastannic acid could be produced by this reaction:

This reaction is just barely possible thermodynamically and was studied in considerable detail by P. D. V. Manning at the California Institute of Technology, but the results of the study have not been published.

To uphold the contention that (1) in respect to stannous oxide in acid solutions wherein the pH is less than 7, sulphur dioxide is an *oxidizing* agent toward stannous oxide; and that (2) in alkaline solutions wherein the pH is greater than 7 sulphur dioxide is a *reducing* agent toward stannous oxide, the data supporting this contention are given in Table III. It will be noticed that the presence of sulphur dioxide is always associated with the formation of dense white or cream colored precipitates in solutions acid in reaction. This precipitate was shown to be a form of stannic acid by chemical tests. In alkaline solutions the presence of sulphur dioxide is associated with the appearance of metallic tin, either as tin crystals, or sponge tin, or as a metal mirror on the walls of the bottle. The presence of tin as such was proven chemically.

All the solutions were in contact with the stannous oxide for a period of several months. Each bottle and its contents had been agitated for 168 hours, excess stannous oxide being in each bottle, in all cases. The bottles were of the four ounce oil sample size. Agitation was caused to take place at 40 R.P.M. which speed allowed the solid particles to completely fall through the volume of the solution, as the bottles were turned over once per revolution of the shaft on which they were mounted.

TABLE III

Solution	Solution Reaction (without SO ₂)	Observation	Conclusion
M/3 Na ₂ SO ₄ ·10H ₂ O Saturated SO ₂	neutral	S ppted., also bulky gray white ppt. whose volume was about 4 times that of original SnO	SnO oxidized
M/1 NaHSO ₃ Saturated SO ₂	acid	S ppted., also bulky white flucculent ppt.	SnO oxidized
M/1 NH ₄ Cl Saturated SO ₂	acid	Yellow sulphur ppted., also white or cream color amorphous ppt.	SnO oxidized
M/2 FeSO ₄ (NH ₄) ₂ SO ₄ Saturated SO ₂	acid	Yellow sulphur ppted., also a white amorphous ppt. in volume 4 to 5 times that of the original SnO	SnO oxidized
M/2 NaCl Saturated SO ₂	neutral	Sulphur ppted., also white precipitate of metastannic acid	SnO oxidized
N/1 NaHSO ₃	acid	Cream colored ppt., of large volume	SnO oxidized
M/1 NaHSO ₃ 2M NaOH	alkaline	Sponge tin metal layer on top of a layer of unchanged SnO	SnO reduced
M/10 Na ₂ SO ₃	alkaline	Small quantity of tin produced as mirror on the side of the bottle.	SnO reduced

Sulphur and tin were both determined chemically in a qualitative manner. All the white or cream colored precipitates were identified as forms of stannic acid by qualitative chemical tests.

To show that the cause of the oxidation is the presence of the SO₂, observations were made in solutions in which SO₂ was not present. Similar solutions in respect to anions and cations were used. They were both alkaline and acid in reaction and were similar to those solutions in which the SO₂ had been used. The results are given in Table IV.

TABLE IV

Solution	Solution Reaction	Observation	Conclusion
M/10 KHSO ₄	acid	No change in layer of undissolved SnO, which was its original brownish black. No sulphur ppt. No white or other ppt. in solution	No reduction or oxidation of SnO
M/1 Mn SO ₄ 4H ₂ O	acid	as above	as above
M/1 NH ₄ Cl	acid	as above	as above
M/2 CuSO ₄ 5H ₂ O	acid	Very thin layer of white substance on top of unchanged brownish black layer of unchanged SnO. White layer not stannic acid as shown by test. S, as such, absent	as above
M/10 MgSO ₄	acid	As M/10 KHSO ₄ above	as above
2M NaCNS	alkaline	as above	as above
M/1 KCN	alkaline	as above	as above

From the data tabulated in this report, it is believed that the conclusion is warranted that in acid solutions sulphur dioxide is an oxidizing agent toward stannous oxide but that in alkaline solutions the reverse is true and that sulphur dioxide there is a reducing agent toward stannous oxide. In acid solutions the reaction favored is of the nature:

while in alkaline solutions the favored reaction is:

The free acid being neutralized by the alkali in the solution to form a sulphate. Sulphates were found by qualitative chemical tests in those solutions originally without sulphates.

It is, therefore, concluded that sulphur dioxide would be valueless in acid solutions as an aid to the solution of tin concentrates. It can not be used in leaching solutions for treatment of tin ores.

Conclusions

Stannous oxide can be readily prepared in a state of high purity if due precautions are taken to have proper pH conditions.

Stannous oxide is thermally unstable above $385^{\circ}\text{C}.$, giving Sn and SnO_2 .

Stannous oxide is readily oxidized by both moist and dry air above $240^{\circ}\text{C}.$ At higher temperatures it is pyrophoric.

Stannous oxide is oxidized by sulphur dioxide in acid solutions; and reduced by the same reagent in alkaline solutions.

The reduction of stannic oxide, reasoning from the data on stannous oxide, is a single step reaction above $385^{\circ}\text{C}.$ and a two step reaction below that temperature.

THE CATALYTIC ACTIVITY OF METALLIZED SILICA GELS

III. The Synthesis of Water

BY L. E. SWEARINGEN AND L. H. REYERSON

Ever since Sir Humphry Davy in 1817 observed that a platinum wire heated below redness, promoted the combination of hydrogen and oxygen, the catalytic synthesis of water has been the subject of much investigation. Because of the relatively simple mechanism of water synthesis it was felt that a study of this reaction would give some idea concerning the catalytic activity of metallized silica gels in oxidation reactions. Morris and Reyerson¹ have shown that metallized silica gels exhibit marked catalytic activity in hydrogenation reactions. Furthermore x-ray studies² have shown that when the metal is deposited upon the surface of the silica gel by the method described, it exists in a very fine state of division. A very large number of active catalytic centers undoubtedly exist under these conditions and the catalysts should exhibit marked activity in oxidation reactions.

Experimental

The metallized silica gels used in this research were the same as those used in the adsorption studies previously reported.³ The gases were streamed at rates varying from 15 to 300 cc. per minute through an apparent volume of 5 cc. of catalyst. The tube carrying the catalyst was maintained in a constant temperature bath and the temperature of the bath was varied from -17° in the case of the platinized and palladized gels to 290° for the copper and silver catalysts. The gas mixtures contained from about six to nine per cent of oxygen, fifty percent hydrogen and the remainder nitrogen.

A gas mixture of approximately the desired composition was first collected in a 20 liter glass bottle. Water was used as the confining liquid. After shaking and allowing to stand for several hours, a sample of the gas mixture was analysed. The gas mixture was then ready for use. An inverted glass bottle full of water supplied the pressure necessary to force the gas mixture through the catalyst train. By regulating the flow of water from the upper to the lower bottle, the velocity of the gas through the catalyst could be varied over a wide range. On leaving the container the gas mixture passed a pressure regulator which was adjusted to just allow gas to escape through it. The gas was then metered by a flow-meter which had been previously calibrated. The gas was dried before entering the catalyst tube by passing through a calcium chloride tube. Metallized gel granules having an apparent volume of 5 cc. were placed on a deep U tube which was similar to the tube described by Morris and Reyerson. A thermometer was kept imbedded in

² Ryerson, Harder and Swearingen: *J. Phys. Chem.*, **30**, 1623 (1926).

³ Reyerson and Swearingen: *J. Phys. Chem.*, **31**, 88 (1927).

the catalyst in order to note any rise in the temperature of the catalyst above that of the bath in which the catalyst tube was immersed. On leaving the catalyst tube the gas was first bubbled through a wash-bottle containing water in order to cool the gases and then led into the gas analysis apparatus. This was a modified Orsat apparatus. It contained absorption pipettes filled with small glass tubes and a water-jacketed gas-measuring burette of 100 cc. capacity. The manifold of the Orsat apparatus was closed with two-way stop cocks in such a manner that the gases flowing from the catalyst could be passed through the manifold by-passed around it. Except during analysis the gas flowed continuously through the manifold. The burette and pipettes were separated from the manifold by glass stop cocks. In this investigation the oxygen content of the gas mixture was the only thing determined. The oxygen was absorbed in an alkaline solution (1500 gm. of KOH per liter of water) of pyrogallol containing 10 gm of pyrogallol acid per 100 gm. of solution.

The catalyst tube was kept immersed in a bath for temperature control. Above 150° solder metal was used, between 100° and 150° Wood's metal was used and below 100° water or ice and ice salt mixtures were used. The bath was well insulated and constant temperatures could be maintained to within a degree or two at the higher temperatures. The temperature was always taken at the time of sampling for analysis.

Experiments were carried out showing the effect of temperature on the combination of hydrogen and oxygen in the presence of the copper and silver gel catalysts. Since the reaction was practically complete at all temperatures in the case of the platinized and palladized gels when the rate of flow was low, a study was made of the efficiency of the catalysts at various rates of flow for several temperatures.

Results

The results of the experimental work are presented in Tables I to IV. When two columns are given under the heading temperature, the column to the left gives the temperature of the bath in which the catalyst tube is immersed while the column to the right gives the temperature as recorded by the thermometer imbedded in the catalyst. In the cases where only one column is given, the temperature recorded was that of the bath. This also indicated that the thermometer in the catalyst recorded the same temperature as that in the bath. Fig. 1 shows graphically the effect of temperature upon the efficiency of copper and silver catalysts in promoting the water synthesis. The rates of flow were low. Fig. 2 illustrates the effect of changing the rate of flow on the efficiency of the more active platinum and palladium catalysts. Three temperatures are given for each catalyst, and the temperatures are those of the bath surrounding the catalyst tube.

Discussion of Results

In the case of the silverized gel, Table I and Fig. 1 show that the reaction became measurable at about 100° . The continuation of the curve indicates a reaction at still lower temperature but this was not realized in the experiments. The catalyst increases in efficiency as the temperature rises. The most rapid increase comes in the temperature interval between 140° and 180° . Above 200° practically all of the oxygen is removed at the rates of streaming studied.

The copper catalyst gives a measurable reaction at a lower temperature than the silver catalyst. The reaction is measurable at 80° . There is a rather steady increase in the amount of reaction until 165° is reached when there is a rapid rise in the efficiency of the catalyst. The catalyst becomes one hundred percent efficient below 200° for the rates of flow of the gas mixture studied. The curves for the silver and copper catalysts are much alike except that above 165° the efficiency of the copper catalyst increases more rapidly than does that of the silver catalyst. This copper catalyst compares favorably with the one prepared by Pease and Taylor.¹ In fact it probably initiates reaction at a slightly lower temperature.

The platinized and palladized gels on the other hand promote complete conversion of the oxygen and hydrogen at all of the temperatures studied provided the rate of gas flow was not too fast. Fig 2 shows the effect of increasing the rate at which the gas streamed through the catalyst upon the efficiency of the catalyst. The efficiency of the catalyst does not diminish as rapidly at the higher temperatures for given increases in gas flow as it does at lower temperatures. These catalysts heat up considerably as a result of the reaction and the temperature is undoubtedly much higher than that recorded by the thermometer immersed in the catalyst because the platinum catalyst was often observed to glow at local points. Tables III and IV show that increasing flow produces increasing differences between the temperature of the bath and that of the catalyst. The platinum catalyst shows a thirty degree rise in temperature at -15° for a streaming rate of 300 cc. per minute. This is the greatest difference observed in any of the experiments. The copper and silver catalysts show no differences in bath and catalyst temperature.

The most interesting result shown by these experiments is that the platinum catalyst is more efficient in promoting the synthesis of water at faster streaming rates than is the palladized gel. This is certainly true at 25° and at -15° . At 0° there is not much difference between the two catalysts. It would also appear that the platinized gel is more efficient at -15° than it is at 0° . This is probably due to the fact that at 0° the water formed by the reaction condenses in small droplets on the wall of the tube. These droplets tend to fall on the catalyst or run down the tube and onto the catalyst. Here the water is vaporized by the local heating of the catalyst granules and this steam tends to prevent the reacting gases from reaching the active surface.

¹ J. Am. Chem. Soc., **44**, 1637 (1922).

At -15° the water freezes on the walls of the tube and does not interfere with the reaction. This no doubt accounts for the almost equal efficiency of the catalysts at 0° while at the other temperatures the platinized gel is considerably more efficient. At slow rates of streaming both catalysts are sufficiently active to use up the oxygen.

The present study does not make it possible to postulate a mechanism of reaction on the catalyst surface because the composition of the gas mixture was not varied.

Summary

1. The silver catalyst initiates the reaction below 100° and is practically one hundred per cent efficient above 200° at the rate of streaming studied.
2. The copperized gel initiates the reaction below 80° and the reaction is complete below 200° .
3. The platinized and palladized gels show marked activity in promoting the synthesis of water at all temperatures studied. The platinized gel is more efficient than the palladium catalyst as the rate of streaming of the gases is increased.

THE CATALYTIC DECOMPOSITION OF FORMIC ACID VAPOUR

BY C. H. D. CLARK AND B. TOPLEY

The catalytic decomposition of formic acid vapour at the surfaces of metals, glasses, silica and metallic oxides can be explained on the view of contact catalysis, according to which the reaction takes place in an adsorbed layer one molecule thick, partially covering the catalyst surface.

The independence of the two alternative modes of decomposition on glass, viz., (1) $\text{HCOOH} \rightarrow \text{H}_2 + \text{CO}_2$, and (2) $\text{HCOOH} \rightarrow \text{H}_2\text{O} + \text{CO}$, when considered in connection with the large temperature coefficients of these two reactions, makes it very probable that the interpretation in terms of the 'adsorption' mechanism is correct in this instance.¹

The simplest assumption to explain the fact of catalysis by surfaces is that the energy necessary for activation of the reactant molecules is lowered by association with the catalytic surface, but this leads one to expect a rough parallelism between temperature coefficient of reaction rate and specific catalytic activity (i.e., the catalytic activity per unit area of superficial surface). Such a parallelism might, of course, be completely masked by a wide variation in the number of molecules adsorbed per unit area; but *a priori* it would seem reasonable to expect that when the heat of adsorption is large, a considerable alteration of the activation energy would be produced, because of the 'molecular field' in which the adsorbed molecule finds itself, and, simultaneously, a *relatively* large fraction of the surface would be covered by the adsorbed layer. Further, the *positive* correction to be applied to the empirical 'energy of activation' in kinetically unimolecular reactions, on account of decreasing adsorption with rise in temperature, is equal to the heat of adsorption. If we write

$$k\alpha\sigma \cdot e^{-A/RT} \cdot e^{+\lambda/RT}, \text{ where}$$

k = rate of reaction per unit area of catalytic surface, under standard conditions of concentration of reactant vapour and volume of reaction bulb;

A = empirical energy of activation obtained from the temperature coefficient of reaction rate;

λ = heat of adsorption per gram-molecule;

R = gas constant;

σ = fraction of surface covered by a unimolecular adsorbed layer, at temperature T ;

then we might expect, in passing from one catalyst to another, that the larger values of σ would be associated with larger values of λ and smaller values of A , so that *qualitatively* there should be a correlation between $e^{-A/RT}$ and k .

Actually, there appears to be no correlation between these two experimental quantities.

¹ Hinshelwood and Topley: J. Chem. Soc., 123, 1022 (1923).

Because of this, measurements of catalytic efficiency have been made for a number of metals, which have not been previously studied with the object of ascertaining whether their specific catalytic activities for one and the same reaction ($\text{HCOOH} \rightarrow \text{H}_2 + \text{CO}_2$) can be related to any one property of the catalysts; for instance, on one view, it seemed possible that catalytic efficiency might be connected with the number of 'free' electrons in the metals, as measured by the excess of their specific heats over the value $3R$. In the event, however, the results were not very helpful from this point of view, because in some cases the actual effects of the metals concerned seemed to be masked by an oxide film; but it has nevertheless seemed worth while to record the experimental results which have been so far obtained.

The experimental method employed was similar to that used by Hinshelwood. The catalyst, together with a weighed amount of formic acid, contained in a narrow capillary with a very fine tip, was introduced into a bulb of known volume, which was cooled in ice, evacuated to below 0.1 mm. with a Hyvac pump, and sealed off. Vapour baths of anisol, aniline, nitrobenzene and quinoline were used to maintain suitable constant temperatures during the decomposition. The unimolecular velocity constant, reduced to 1 sq. cm. of catalyst surface in a 20 c.c. reaction bulb, is taken as a measure of the specific catalytic activity. This constant will be denoted by k .

Some experiments with osmium and tungsten were also carried out in a manometric apparatus exactly like the one already described.¹ Analyses of the gaseous products of decomposition were carried out in a Haldane apparatus.

Catalysis by Osmium

The use of osmium as a catalyst was suggested by the observation of E. Müller and K. Sponzel² that, in respect of decomposition of aqueous solutions of formic acid, the activity of metallic rhodium decreases as the purity of the metal increases, and appears to be connected with traces of osmium in the rhodium.

Metallic osmium was obtainable only in the form of a powder. A rough estimate of the effective surface of this powder was made by determining the size of the grains. The particles were 'graded' by sifting through fine copper gauze, and the number of particles determined in two ways:—

(1) By counting under a microscope the number of particles in a weighed amount of the powder; this gave 3.71×10^6 particles per gram.

(2) By the application of Stokes' Law, which gave 1×10^6 particles per gram.

From the mean of these results, the surface area of 1 gram of the powder is calculated to be 80.1 sq. cm. This represents the order of magnitude of the superficial area of the osmium catalyst.

The experiments with osmium were done with 90% formic acid. For decomposition at temperatures in the neighbourhood of 200°C, analysis of the

¹ Hinshelwood and Topley: J. Chem. Soc., 123, 1022 (1923).

² Z. Elektrochemie, 28, 307 (1922).

reaction products showed that only hydrogen and carbon dioxide were produced. The reaction follows the unimolecular law, as the results in Table I of a typical experiment in the manometric apparatus show.

TABLE I

Time <i>t</i> (minutes)	Pressure <i>p</i> (mm. of Hg)	$k = 1/t \log_e p_\infty / (p_\infty - p)$
20	116	0.00655
40	197	0.00645
60	267	0.00679
80	314	0.00671
100	349	0.00685
End Point	440	

The absolute value of the velocity constant was determined at 153.9°C, in a series of five sealed bulb experiments, the results being $k = 0.0131$, 0.0078, 0.0146, 0.00767 and 0.00903. The average value of the unimolecular constant $k_{CO_2} \pm 0.0104$.

The temperature coefficient was found by using the device of allowing the reaction to take place partly at one temperature, and then to proceed to completion at a higher temperature, in the manometric apparatus. The results of experiment are given in Table II.

TABLE II

Temperatures (°C)	k_{CO_2}	A_{CO_2} (cals.)
154.6	0.00477	18,900
185.0	0.0209	
154.25	0.00241	19,300
185.0	0.0111	
154.9	0.00319	18,400
185.1	0.0133	

The value of *A* may be taken as 19,000 calories per gram, to the nearest 500 calories. Using this, the absolute magnitude of the unimolecular constant per unit area for a 20 c.c. bulb, is calculated to be 9.2×10^{-2} at 200°C.

Catalysis by Nickel

The nickel catalyst was used in the form of pure nickel foil. At the temperatures of the experiment (183° and 210°) the formic acid vapour (99.6%) reacts with the metal, hydrogen being formed; after the reaction, the bulb contained drops of a greenish liquid,—presumably a solution of nickel formate. At the same time, carbon dioxide is formed in the reaction bulb, probably as a result of direct catalytic decomposition at the metallic surface, and not by the decomposition of nickel formate, since there was no sign of a deposit of metal on the smooth surfaces of the foil.

In a typical experiment at 210° , the gas in the reaction bulb had the composition:

$$\begin{aligned} \text{H} &= 64.3\% \\ \text{CO}_2 &= 33.7\% \\ \text{CO} &= 2.0\% \end{aligned}$$

The 2.0% of carbon monoxide corresponded to the activity of the walls of the reaction bulb, which was of soda glass.

Similar results were obtained in other experiments, though the ratio of carbon dioxide to hydrogen is somewhat variable, and increases at the lower temperature.

Under the conditions of these bulb experiments, there is no formation of methane by reduction of carbon dioxide by hydrogen, as observed by Sabatier with a finely divided nickel catalyst. Westcott and Engelder,¹ also obtained no methane when decomposing formic acid vapour by passing it over a nickel catalyst between 200° and 500° .

On the assumption that the carbon dioxide is formed by the usual unimolecular reaction, independently of the simultaneous interaction of the nickel and formic acid vapour, the following rough values of k_{CO_2} (calculated with natural logarithms, the unit of time being the minute) are a measure of the specific catalytic activity of nickel:—

	k_{CO_2} per 1 sq. cm.
183°C	3×10^5
210°C	1.6×10^{-4}

For comparison with other catalysts, the absolute magnitude of the unimolecular constant for nickel at 200°C may be taken as 1.0×10^{-4} .

Catalysis by Tungsten

The catalyst was used in the form of a thin tungsten sheet. Catalytic decomposition takes place at a rate convenient for measurement at 210°C ; a manometric experiment proved that the reaction follows the unimolecular law.

The gaseous reaction product was practically pure carbon monoxide. During the reaction, the bright surface of the tungsten becomes dull and slightly blue. Since all other *metals* that have been experimented with catalyse the carbon dioxide reaction mainly, it seems likely that the explanation of the production of carbon monoxide only in this case is that a thin film of the blue oxide of tungsten is rapidly formed on the surface of the metal, which then produces the usual catalysis by oxides yielding carbon monoxide. This would account for the discolouration of the metal, and, moreover, an experiment in which the yellow oxide of tungsten was heated at 210°C in a sealed bulb with formic acid vapour resulted in the reduction of the yellow to the blue oxide.

¹ J. Phys. Chem., 30, 476 (1926).

The existence of such a thin film of oxide on tungsten is probable, according to U. R. Evans,¹ in view of the marked passivity of the metal. The reaction bulb was evacuated to rather less than 0.1 mm. of residual air, which would leave sufficient oxygen to furnish an oxide film thick enough to produce interference colours.

An interesting point is the unusual catalytic activity of this oxide film; the unimolecular constant k_{CO} per sq. cm. of superficial area of oxide layer is 2.5×10^{-5} at 210°C . This is rather higher than the constant k_{CO} for silver at the same temperature, and certainly very much greater than the specific activity of ordinary granular "blue" oxide of tungsten; possibly the association of the coherent oxide film with the underlying metal alters its properties.

Catalysis by Molybdenum and Tantalum

Both molybdenum and tantalum catalyse the decomposition, but the usual reaction $\text{HCOOH} \rightarrow \text{H}_2 + \text{CO}_2$ is not the main effect. A typical analysis of the gas obtained with molybdenum was:—

$$\begin{aligned}\text{H} &= 53.4\% \\ \text{CO}^2 &= 6.7\% \\ \text{CO}^2 &= 39.9\%\end{aligned}$$

About one-third of the carbon monoxide and a little of the carbon dioxide in this experiment would have been due to the catalytic action of the soda glass of the reaction bulb; the excess of hydrogen is thus very marked. The interaction of formic acid and molybdenum is being further investigated.

Catalysis by Silica, Pyrex and Soda Glass

In the course of the experiments on metals, an attempt was made to find a material for the reaction vessel which would have a negligibly small catalytic activity. The specific activity of silica and of Pyrex was compared with that of soda glass. At 210°C , the products are mainly carbon monoxide and water in each case. The means of the results of many experiments are represented by the following figures:—

	k_{CO}
Soda Glass	4×10^{-6}
Pyrex	1.5×10^{-6}
Fused Silica	1.0×10^{-6}

Table III contains the quantitative data available as to the catalytic decomposition of formic acid vapour on the surfaces of different catalysts; the values of k are calculated in reciprocal minutes, for unit surface of the catalyst in a reaction bulb of 20 c.c., using natural logarithms.

THE EFFECT OF TEMPERATURE ON RATE OF OSMOSIS

BY RALPH N. TRAXLER

It is a commonly recognized fact that rise in temperature causes a marked increase in the rate of osmosis and dialysis and also increases the osmotic pressure developed by a solution separated from the pure solvent by a semipermeable membrane. A review of the literature covering these subjects shows that relatively little attention has been given to the effect of temperature except in its direct effect on the osmotic pressure of a solution. H. N. Morse and his coworkers¹ and numerous others have investigated this phase of the subject quite extensively. However, nothing in a quantitative way is recorded concerning the rate of passage of material through a membrane as affected by temperature.

G. Flusin has shown by experiments on rubber membranes² and on pig's bladder³ that the direction and velocity of transfer of liquids across these membranes depend on the absorption capacity of the membrane for the liquids. Carbon disulphide which is absorbed readily by rubber passes quickly through a rubber membrane into alcohol, whereas chlorobenzene and nitrobenzene which are not readily absorbed pass through very slowly. Water which is taken up in large quantities by hog's bladder passes through rapidly and chloroform which is absorbed much less passes through proportionally slower. He decided that the velocity of osmosis did not depend on the maximum amount of absorption but upon the energy with which the membrane takes up the liquid during the first minute of contact. His experiments were carried out under controlled temperature conditions, but no attempt was made to determine the effect of different temperatures on the velocity.

The present paper records the results of experiments made to determine the effects of definite changes of temperature on the rate of establishment of equilibrium in (1) a system composed of pure pyridine separated from pure water by a thin rubber membrane and (2) a system composed of a one-half molar solution of sodium chloride in water separated from pure water by a collodion membrane.

Experiments showing the Effect of Temperature Changes on the Passage of Pyridine through a Thin Rubber Membrane into Water.

The pyridine was pure and freshly distilled before use. The water was distilled and free from dissolved gases. The rubber used for the membrane was a high grade of dental dam, very uniform in weight and quality. The thickness of the unstretched sheet was $0.3 \pm .05$ mm.

² Compt. rend., **126**, 1497 (1898).

³ Compt. rend., **131**, 1308 (1900).

No originality is claimed for the cell and stirring arrangement, the design of which was derived from the apparatus used by Kahlenberg¹ in his work on osmosis and dialysis. Fig. 1 gives the essential details of the apparatus.

The cell was a cylindrical nickel-plated drum, 3 centimeters in diameter and 4.2 centimeters in height. The area of the open end was 7.07 square centimeters. Around the bottom and open end of the drum was a rolled

FIG. 1

flange which made it easy to fasten on the membrane. A bar was fastened across the inside of the cell about 0.5 centimeter from the bottom, the function of which was to prevent the stirrer from dropping down into direct contact with the membrane. The upper and closed end of the cell was fitted with a metallic tube 5 centimeters long and exactly the same diameter as a glass tube which was firmly fastened to it by means of rubber tubing and wire. A hollow cylinder carrying a large number of turns of fine wire formed an electro-magnet which operated the stirrer. This electro-magnet was connected to a source of direct current through a rheostat and adjustable make and break contact. The long glass tube extending up from the cell rested against a millimeter scale upon which the rise of the liquid in the cell could be conveniently read. The rubber membrane was tied over the mouth of the cell by means of strong thread, care being taken to obtain a taut surface without

¹ J. Phys. Chem., 10, 141 (1906).

stretching the rubber. After the rubber was in place a piece of new, washed muslin, weighing 0.0133 gram per square centimeter was tied over the mouth of the cell. Some such support was obviously necessary to prevent the bulging and stretching of the rubber under the weight of the column of liquid. New pieces of rubber and cloth were used for each experiment.

FIG. 2

The cell, filled with water and free from air bubbles and with the meniscus on the scale, was placed in a glass cup or beaker containing the pyridine. The beaker was covered by a slit cover fitting around the cell, and then placed in a thermostat capable of regulation to less than 0.5°C. The cell was always immersed to the same depth in the pyridine. The water in the cell and the pyridine in the beaker were brought to the temperature of the thermostat before lowering the cell into position.

The rise of the liquid in the glass tube was observed and recorded in centimeters. By careful calibration it was found that the tube, which was excep-

tionally uniform in bore, contained 52 cubic millimeters for every centimeter of its length. From this the scale readings were converted into volumes passing through the membrane. Dividing this value by the area of the membrane gave the volume passing through one square centimeter. These are the values used in plotting the results.

Stirring of the inner liquid took place every 18 or 20 seconds. Kahlenberg¹ has shown that stirring is absolutely necessary in quantitative measurements of osmosis and osmotic pressure. His contentions in regard to this point of technique were again shown to be correct in the experiments herein recorded. More or less rapid and uniform stirring was necessary in order to obtain uniform and concordant results in the experiments recorded below. It is only reasonable to assume that, without stirring, the pyridine passing through the rubber would form a very concentrated solution of pyridine in water which would remain in close proximity to the membrane. The pyridine would only diffuse slowly into the water in the upper part of the cell. This layer of concentrated solution would retard the flow of pyridine through the membrane. A false equilibrium would thus be set up between this layer and the pure pyridine emerging from the membrane. The purpose of the experiments is to measure the rate of attainment of equilibrium between the uniform contents of the cell and pure pyridine. Stirring the contents of the cell causes the concentration to be maintained nearly uniform throughout.

Experiments were conducted at ten degree intervals from 5°C. to 85°C. The results are given in Tables I to IX and are plotted in Fig. 2. Checking experiments were made at each temperature. To conserve space the averages are given in the tables, except at 35°C. where two runs are given to indicate the small differences usually occurring. At 65°, 75° and 85°C. the amount of error increases slightly due probably to the greater difficulties of manipulation at the higher temperatures. Toward the end of the experiments at these higher temperatures the rate of passage increased somewhat. This is shown

by the upward trend of the curves at 65°, 75° and 85°. This result is undoubtedly due to the solvent action of the hot pyridine on the rubber, causing the membrane to be thinner at the end of the experiment than it was at the beginning. The membranes in contact with pyridine at a temperature of 85°C. were so far disintegrated at the end of 70 to 80 minutes that they would no longer sustain the column of liquid.

Experiments showing the Effect of Temperature Changes on the Passage of Sodium Chloride from a One-half Molar Solution through a Collodion Membrane into Water.

The sodium chloride was purified by precipitation with hydrogen chloride. The water was distilled and had been boiled to free it from dissolved gases. The collodion sack was prepared by pouring an alcohol-ether solution of nitro-cellulose into a large test tube, rotating the tube and draining out the excess solution. After a short time had elapsed the membrane was removed from the tube and washed thoroughly in distilled water. The membrane was perfectly transparent.

A large cork stopper which had a large hole cut in the center and which had been thoroughly covered on its entire surface with collodion was fitted into the mouth of the sack. The sack itself was 13 centimeters long and 4 centimeters in diameter. When 100cc. of solution were placed in the sack 85 square centimeters of surface were presented for dialysis.

The bag was suspended in a one and one-half liter beaker by means of a wire clamp attached to the cork and fitted over the side of the beaker. The beaker was immersed in the same thermostat used in the experiments with rubber membranes. A glass stirrer passed through the hole in the cork stopper and effectively agitated the contents of the sack. Another stirrer circulated the contents of the beaker. 100cc. of the salt solution were placed in the bag and 1200cc. of distilled water in the beaker. The solution and the water in the beaker were both brought to the temperature of the thermostat before lowering the sack into the water.

10cc. samples were drawn every 5 minutes from the beaker. The contents of the beaker were agitated with a current of air just before drawing each sample. This was done to make certain that there was not a layer of concentrated solution at the bottom of the beaker which had not been completely eliminated by the action of the mechanical stirrer. 10cc. of pure water at the temperature of the experiment were added for every 10cc. of solution withdrawn. Corrections were made for this continual dilution.

The chloride was determined in each sample drawn by means of a $N/100$ solution of silver nitrate, using potassium chromate as indicator.

Experiments were performed at ten-degree intervals from 25°C . to 65°C . Two or more experiments were conducted at each temperature and it was found possible to check within small margins between two runs at the same temperature. The quantity of salt in the system at the end of a run as calculated from the analytical results checked the amount in the original 100cc.

FIG. 3

of one-half molar solution within 0.15% to 0.20%. When the transfer of sodium chloride became almost zero the contents of the sack in each experiment measured approximately 110cc, indicating a flow of water through the collodion membrane toward the salt solution.

The same membrane was used for the first seven runs. This membrane was accidentally broken and a new one had to be prepared. To determine whether results from two different membranes were comparable, some of the determinations made with the first membrane were repeated with the new one. These determinations checked almost as closely as those made with the same membrane. It is thus possible to prepare two collodion membranes from the

same material and following the same procedure which will show the same rate of permeability to a soluble salt such as sodium chloride. It should be noted at this point that the membranes were soaked thoroughly in distilled water between experiments.

FIG. 4

The amount of sodium chloride in milligrams passing through one square centimeter of the collodion membrane in five minutes was calculated from the analytical data. These are the values given in column three of Tables X to XIV and used in plotting against time in Figs. 3 and 4.

Discussion

The rate of passage of pyridine through thin rubber membranes increases with rise in temperature. Approximately, the velocity at 15°C is double that at 5°C and at 25°C it is twice as much as at 15°C. At 35°C the rate is 50 percent greater than at 25°C and the velocity at 45°C is also 50 percent greater than at 35°C. The rate at 55°C is 33 percent greater than at 45°C and at 65°C it is one third larger than at 55°C. The increase between 65° and 75°C and between 75°C and 85°C appears to lie in the neighborhood of 33 to 25 percent.

Any explanation of such experimental results is necessarily rather speculative. The ideas of Armstrong¹ and Gillet² offer a rather attractive explanation of the observed results. Water is considered as an equilibrium mixture of hydrol (H₂O), dihydrol (H₂O)₂ and polyhydrol (H₂O)_n. The equilibrium between these forms is affected by temperature; the higher the temperature the greater the amount of hydrol (H₂O) present. This "monad" is very reactive

¹ Proc. Roy. Soc., 78A, 264 (1906).

² Compt. rend., 177, 257 (1923).

and is chiefly responsible for the chemical activities of water. The introduction of foreign materials into water which are soluble in the liquid tend also to disturb the equilibrium in the direction $(\text{H}_2\text{O})_n \rightarrow n\text{H}_2\text{O}$.

At the lower temperatures the amount of (H_2O) present is relatively small. It is this hydrol (H_2O) which attracts the pyridine and removes it from the surface of the rubber membrane. It would appear from the data given above that from 5°C to 25°C the production of (H_2O) under the influence of temperature is regular and about doubles for each 10 degree increase provided the attraction of water for pyridine may be taken as a measure of the amount of hydrol present. Above 25°C the relative effect of temperature on hydrol formation (and attraction of water for pyridine) becomes less; up to 45°C being about a 50 percent increase for each 10 degree interval and from there up to 65°C showing a 33 percent increase for a like interval. Above 65°C the amount of hydrol (H_2O) present in the equilibrium mixture is so large that an increase in temperature has relatively less effect.

The uniformity of the rates for temperatures from 5° to 65°C after the first 30 minutes may be explained by the fact that sufficient pyridine has entered by that time to combine with the hydrol originally present. The dihydrol and polyhydrol present are continually dissociating under the effects of the temperature of the experiment. The hydrol thus liberated combines immediately with pyridine and the dissociation continues, the rate being governed by the temperature. An excellent example of this was shown in an experiment not recorded above which was allowed to run at 25°C for seven and one-half hours. No material change in rate was noted over the last seven hours of the experiment.

At the high temperatures, 75° and 85°C , complications arise because of the vigorous action of the hot pyridine on the rubber. The membranes gave way entirely after exposure to pyridine at 85°C for 70 to 80 minutes. It is evident, however, that increase in temperature at these higher levels would have relatively less effect. The equilibrium mixture would contain a preponderance of hydrol with some dihydrol and relatively little polyhydrol, consequently a temperature change would have a smaller effect on the production of (H_2O) in proportion to the amount originally present than would a like change at a lower temperature where less hydrol and more of its polymers were present in the original equilibrium mixture.

The above reasoning ignores the effect of the membrane on the rate of passage of the pyridine through it. This factor is one that must be recognized. Pyridine dissolves in rubber and the water (hydrol, H_2O) on the upper side of the rubber removes the pyridine from the surface. Increase in temperature increases the solubility of pyridine in rubber so that the effect of the membrane in this particular case tends to be in the same direction as the other effects mentioned above.

In the case of the passage of sodium chloride from an aqueous solution through a collodion membrane into water it is more difficult to draw conclusions. There is transfer in both directions because water passes through the collodion membrane into the salt solution at the same time that the salt

passes through into the water. In other words the membrane in this system is not at all semipermeable. Equilibrium tends to be established with the concentration of the salt the same on both sides of the membrane. The higher the temperature the more rapidly the salt passes through the membrane *at first* but the rate of passage is very nearly the same for all temperatures between 25°C and 65°C at the end of 30 minutes.

Summary

1. The volumes of pyridine in cubic millimeters passing through one square centimeter of rubber dam into pure water at temperature intervals of 10 degrees from 5°C to 85°C were determined.
2. The rate increases 100 percent for 10 degree intervals between 5°C and 25°C; 50 percent between 25°C and 45°C; 33 percent between 45°C and 65°C; and from 33 to 25 percent for 10 degree intervals between 65°C and 85°C.
3. The milligrams of sodium chloride from a one-half molar aqueous solution passing through one square centimeter of collodion membrane into water were determined for 10 degree temperature intervals between 25°C and 65°C.
4. The *initial* rate of passage of the salt through collodion is greater the higher the temperature, but the rate is practically the same for all temperatures at the end of 30 minutes of dialysis.
5. The reasons for the results obtained in the experiments on pyridine are discussed from the viewpoint of the theory that water is an equilibrium mixture of hydrol (H_2O) and its polymers.

The author wishes to express his indebtedness to Mr. Harry N. Huntzicker for his assistance in the experimental work on the pyridine-rubber-water system.

GALLIUM. I. ARC SPECTROGRAPHIC DETECTION AND ESTIMATION OF GALLIUM. II. EXTRACTION OF GALLIUM FROM LEPIDOLITE¹

BY JACOB PAPISH AND DONALD A. HOLT

I. Arc Spectrographic Detection and Estimation of Gallium

General. Arc spectroscopy is well suited to the needs of the analytical chemist. When the visible and the ultraviolet spectral ranges are considered it will be noticed that the great majority of metals and a number of non-metals have their persistent lines in these ranges. Arc spectra, as a rule, are intense and this makes them especially adaptable to spectrographic observation. If the substance to be analyzed is a good conductor of electricity, such as a metal or an alloy, and is in the form of wire or rod, it can be used directly as electrode material. Ordinarily the chemist is confronted with the handling of substances that are non-conductors; even in the case of metals he has to work frequently with granules, powders, borings and lumps which cannot be made into electrodes, at least, not conveniently. In such cases and also in the case of liquids, use is made of graphite rods of suitable diameter and length to hold the substances to be subjected to spectral excitation. Artificial graphite of a very high degree of purity is procurable for spectroscopic work. When an arc is made between two such graphite rods, the spectrum will be found to contain, in addition to the lines and bands due to carbon and to some of its compounds, also lines due to a number of impurities such as magnesium, sodium, calcium, lithium, silicon, iron and manganese. Other things being equal, the intensity and the number of these lines will depend upon the quantities of the respective impurities.

The direct current is used for the production of the arc, and it is the practice to make the lower electrode the anode. The anode is considerably hotter than the cathode. This fact can be observed any time on breaking the arc: the anode will be red-hot over a longer distance and it will continue to glow some time after the cathode has become dark. When the lower electrode is made the anode, and the substance to be analyzed is placed on it, it will be observed that the spectroscopic test, in a great many cases, is much more sensitive than in the event of reversed polarity.

A quartz spectrograph fitted with one Cornu prism, or a larger auto-collimating Littrow type of instrument, is suitable for work in the ultraviolet region. The latter instrument gives very good results also in the visible range. For the detection of gallium which has persistent lines in the visible, a glass instrument can be used. Ordinary photographic plates with a sensitivity between λ 5000 and λ 2350 give very good results, and of course special plates should be used for ranges other than this. The method of developing

¹ The experimental work described in this article was made possible through a grant from the Heckscher Foundation for the Advancement of Research, established by August Heckscher at Cornell University.

and fixing is similar to the one followed in ordinary photographic work with one outstanding difference: In spectrography the chemist is after hardest contrasts obtainable.

Experimental Work with Gallium. Freshly precipitated gallium hydroxide, which on spectrographic examination was found to contain only negligible traces of sodium, iron, calcium, magnesium and silicon, was converted to the chloride with the aid of hydrochloric acid. The gallium content of this solution was determined gravimetrically and water was added to bring the concentration to 0.1 percent. From this stock solution, solutions containing 0.01, 0.001 and 0.0001 gm. of gallium per 100 cc. were prepared. A small, definite portion (0.1 cc.) of each solution, delivered from a graduated capillary pipette, was placed on the lower graphite electrode and subjected to arc excitation. These portions contained 0.1, 0.01, 0.001 and 0.0001 mg. of gallium respectively. Fresh electrodes were used in connection with each test. The spectral lines observed at the different concentrations are recorded in Table I.

TABLE I

λ	0.1 mg.	0.01mg.	0.001mg.	0.0001mg.
4172.0	v	v	vf	
4033.0	v	v	vf	
2944.2	v	v	f	
2943.6	v	v	v	f
2874.2	v	v	v	f
2719.7	v	v	vf	
3659.9	v	v	vf	
2500.2	v	v	vf	
2450.1	v	f		
2338.6	vf			

Note. "V" designates the fact that the line is visible, "f", that it is faint and "vf" that it is very faint

If gallium in quantities larger than 0.1 mg. be arced, the following spectral lines, in addition to those given in Table I will be observed: 3020.5, 2418.7, 2371.3, and 2249.2. Because the human eye is much more sensitive to visible radiation than the photographic plate, λ 4172.0 and λ 4033.0 are visible when the concentration of gallium is lower than the lowest given in the table. This is especially true of the lower frequency line. The gallium line 2874.2 is coincident with an iron line of practically the same wave length. It should be borne in mind, however, that this iron line is of low persistence, and if it is visible, many other lines due to this element should be present.

Fifty-five minerals were examined spectrographically for the presence of gallium. The observations are recorded in Table II. The term *trace* as employed in this table designates quantities in the neighborhood of 0.001%; *large trace*, stands for quantities in the neighborhood of 0.01% and *small trace* for quantities less than 0.001%. To illustrate how these have been arrived at, the case of lepidolite (from San Bernardino County, California) will be briefly considered.

Muscovite	Asheville, North Carolina	Trace
Natroloite	Medford, Oregon	Trace
Nephelite	Bancroft, Ontario	Trace
Oligoclase	Orange County, New York	Trace
Orthoclase	Quebec	Small trace
Orthoclase (pebble)	Pacific Grove, California	Trace

TABLE II (Continued)

Mineral	Place of origin	Ga content
Sodalite	Litchfield, Maine	Small trace
Sodalite	Hastings County, Ontario	Small trace
Spodumene	California	Trace
Stilbite	Peekskill, New York	Absent
Stilbite	West Paterson, New Jersey	Absent
Tourmaline	El Paso County, California	Large trace
Tourmaline	San Diego County, California	Large trace
Tourmaline	Winter Harbor, Maine	Trace
Tourmaline	Richland, New York	Trace
Tourmaline	Bedford, New York	Trace
Turquois	New Mexico	Absent
Wavellite	Montgomery County, Arkansas	Absent
Willemite	Franklin Furnace, New Jersey	Absent

Finely powdered lepidolite in five and ten milligram portions was subjected to arc excitation. The spectrograms in the case of the higher quantity contained the gallium lines 4172.0, 4033.0, 2944.2 (faint), 2943.6 and 2874.2. This would seem to indicate that a quantity higher than 0.001 mg. and lower than 0.01 mg. of gallium was present in the zone of excitation. Expressed in percentages, the gallium content is estimated to be between 0.001 and 0.01. The shortcomings of this method of estimating the quantity of an element are obvious: The reactions in the arc are beyond the control of the operator. However, if the limits are wide, it is possible in many cases to differentiate between traces and larger quantities, especially if the element has spectral lines of great sensitivity.

II. Extraction of Gallium from Lepidolite

The mineral, ground to pass through a 40 mesh sieve, was fused in a nickel crucible with twice its weight of potassium hydroxide, and while still in a pasty condition, the fused mass was broken up in small particles by stirring with an iron rod. It was transferred to a tall glass cylinder containing water, stirred with a current of air and allowed to settle. The supernatant liquid was siphoned off, more water was poured in the cylinder, stirred as before; the solid was again allowed to settle and the liquid was removed. This was repeated till about ten liters of water were used for one kilogram of original mineral. The residue which contained practically all the aluminum and all the gallium, a fact established spectroscopically, was placed in an evaporator, treated with concentrated hydrochloric acid and heated to "crack" the silica gel. The aluminum and gallium were extracted with successive portions of dilute hydrochloric acid and the extraction was deemed completed when the residual silica showed no gallium or the merest traces when examined spectroscopically. The chloride solution was concentrated to a small volume

and the excess of mineral acid was neutralized with ammonium acetate and an excess of acetic acid was added. Potassium arsenite was added to this and the whole was first saturated with sulphur dioxide to make sure that the arsenic is in the trivalent state, and next with hydrogen sulphide. The galliferous arsenious sulphide was removed by filtration. But the filtrate was not entirely free from gallium, and in order to recover this fraction it was necessary to repeat the procedure of adding potassium arsenite and saturating with sulphur dioxide and with hydrogen sulphide until a precipitate of arsenious sulphide was obtained which did not carry gallium. The galliferous precipitates were transferred to an evaporator and treated with nitric acid. The unoxidized sulphur was removed by filtration and washed till it was found to be free from gallium. The excess of nitric acid in the filtrate was driven off by evaporation and hydrochloric acid was added. The solution was saturated with sulphur dioxide and with hydrogen sulphide and the precipitated arsenious sulphide was removed by filtration. It was found on spectroscopic examination that even this residue on careful washing with hydrochloric acid retained minute traces of gallium. The filtrate which contained aluminum and gallium was concentrated to a small volume, made strongly acid with hydrochloric acid and an excess of potassium ferrocyanide was added to it. This brought about the precipitation of gallium as the ferrocyanide together with a comparatively large quantity of ferrocyanic acid. Since gallium ferrocyanide, like other ferrocyanides, is peptized by adsorption of the ferrocyanide ion, it was found necessary to employ egg albumin to facilitate the removal of the solids by filtration. The residue thus obtained was washed on the filter with dilute, warm hydrochloric acid until washings gave no test for aluminum. The residue and filter were ignited. Aqua regia was added and heat applied until complete solution was brought about. Successive portions of hydrochloric acid were next added and driven off by evaporation to insure the removal of the oxides of nitrogen. The hydrochloric acid in turn was neutralized with ammonium acetate; acetic acid was added and the iron was precipitated out by adding a freshly prepared hot solution of α -nitroso- β -naphthol in 50% acetic acid. The iron precipitate, when separated from the solution and washed on the filter, was found on spectroscopic examination to be free from gallium. The filtrate was made alkaline with ammonium hydroxide and boiled until gallium hydroxide precipitated out. This was removed by filtration, washed and ignited to the oxide. A spectrographic examination of the freshly precipitated gallium hydroxide proved that it contained negligible traces of the commoner elements ordinarily associated with substances of highest purity. The ignited oxide contained the same impurities, especially silicon and magnesium, to a somewhat higher degree. These, evidently, were derived from the incinerated filter paper.

One kilogram of lepidolite treated in the manner just described yielded 0.0887 gm. of Ga_2O_3 . The gallium content of the mineral expressed as percentage is very close to 0.007.

Summary

A method for the arc spectrographic detection and estimation of gallium was described.

Fifty-five minerals were examined spectrographically for the presence of gallium and the results recorded.

A method for the extraction of gallium from lepidolite was described.

Cornell University.

NEW BOOKS

Recent Advances in Organic Chemistry. Vols. I and II. By Alfred W. Stewart. Fifth edition. 22 × 15 cm; Vol. I, pp. xiv + 387; Vol. II, pp. xiv + 382. London and New York: Longmans, Green and Co., 1927. Price \$7.50. The first volume contains "a survey of numerous fundamental problems of organic chemistry, and, with some few exceptions, it deals with subjects upon which general agreement has now been reached." The chapters are entitled: some main currents in organic chemistry; sundry modern reagents; addition reactions; the aliphatic diazene compounds; the ketens; the polyketides and their allies; the monocyclic terpenes; the dicyclic terpenes; the olefinic terpenes; the pyrrol, pyridine, and tropine alkaloids; the quinoline and isoquinoline alkaloids; the purine group; the polypeptides; trivalent carbon; unsaturation; orienting influences in the benzene system; conclusion.

"In every science which is at all progressive there must arise from time to time conflicts between the older generation of workers and the leaders of the new; for, to those who have grown up along with it, a theory generally becomes invested with a sanctity which is quite out of keeping with its true make-shift character. The longer a theory stands, the harder it is to shake it, and the greater is the tendency to become stereotyped. There is another side to the matter. Without any disrespect, it may be said that the majority of scientific investigators are not possessed of strikingly original minds—we cannot all be Pasteurs—and hence there is a pronounced tendency to take things as they are and work along the beaten track rather than to push out in the wilderness and risk the chance of losing the road altogether. Thus round every theory there grows up a little band of workers, whose one aim seems to be to accumulate evidence confirming their favorite hypothesis; and in this way the theory gains considerable weight of supporting data. On the other hand, the solitary worker who happens to differ from the majority of his fellows has to overcome a tremendous weight of unconscious prejudice before he is able to obtain even the semblance of an impartial hearing. In spite of these difficulties, however, progress is made," p. 1.

"When the recent progress of organic chemistry is compared with the tremendous revolutions in inorganic chemistry and radioactivity which have been brought about by the work of Thomson, Ramsay, Rutherford, Soddy, Aston, and Lewis, the contrast cannot but strike the mind.

"One reason for this comparative barrenness is perhaps to be found in the attraction which the newer subjects have exercised upon investigators, drawing the more original minds away from organic problems. The formula of triphenylmethane is certainly a less entrancing subject than, say, the peculiar phenomenon of isosterism; and it is only natural that inquiring intellects should concentrate themselves by preference upon matters which seem more fundamental than problems of molecular structure.

"There is, however, no reason to despair of the future of organic chemistry. It is true that the mere synthesis of a large number of new substances or even the clearing-up of the constitution of some intricate alkaloid will not lead to a fresh avatar of the subject. What is urgently needed is a completely new line of development. It is not difficult to suggest ways in which such a change of trend might be accomplished. For example, nine-tenths at least of our laboratory reactions lie outside the temperature-limits under which the plants and the animals exist, yet plants and animals succeed in producing quite considerable yields of certain materials which we can obtain in the laboratory only with some difficulty. It seems not impossible that a study of reactions which can take place at ordinary temperatures and in the absence of violent reagents, might open up an entirely fresh line of development in organic chemistry. Our increased modern knowledge of catalysts and their action makes this field much more promising than it once was; and the possibilities involved in the use of colloidal reagents need only be mentioned in order to suggest lines of investigation which could hardly prove unfruitful," p. 17.

"Although the word "alkaloid" is one of the best known in chemical terminology, an exact definition of its meaning is by no means simple. For present purposes, a general idea of alkaloidal character is more important than an academic definition; and the following description will suffice here.

"The alkaloids are naturally-occurring nitrogen compounds which possess certain specific physiological actions upon animal organisms. Thus atropine has a mydriatic effect and is used for expanding the pupil of the eye; quinine is employed as a febrifuge to reduce temperature during fever; strychnine produces the muscular effects noticed in cases of strychnine poisoning; and cocaine acts as a local anaesthetic. In the majority of alkaloids, but not in all, the nitrogen atom is a member of a ring-system such as pyrrol, pyridine, or quinoline; and even in cases where it is a part of an open chain it is either secondary or tertiary in character. In consequence, the majority of alkaloids have basic characteristics; but this is not an invariable rule, since some of the purine group are acidic in their nature.

"On examination of the more familiar alkaloids it is found that they are built up on the basis of the pyridine ring, just as the aromatic compounds are founded on the benzene nucleus; and as among aromatic types a benzene ring is sometimes found to be condensed with other cyclic chains, so in the pyridine alkaloids there are compounds wherein the pyridine ring is overlaid with others, yielding derivatives of quinoline or isoquinoline," p. 205.

"The main characteristics of the polypeptide class may now briefly be summarized, and it is of interest to compare them with those of the naturally occurring proteins. The polypeptides are solids, which usually melt at about 200°C, with some decomposition. They are easily soluble in water, but insoluble in alcohol, like some of the albumins; and instead of having the usual insipid or sweet taste of the ordinary amino-acid, they are bitter, like the protein derivatives. In dilute sulphuric acid solution they are precipitated by phosphotungstic acid, in which behavior they resemble the albumins. Both the natural and artificial classes give the biuret reaction. The action of ferments, or of acids or alkalis, is the same in both classes; and similar products are obtained when animals are fed with polypeptides and albumins. In the case of ferment action it is found that much depends upon the groups which have been used in building up the polypeptide structure, some polypeptides being much more easily fermented than others," p. 279.

"According to Gomberg, all the important properties of triphenylmethyl can be explained on the basis of the following hypothesis: (1) tautomerization of hexaphenyl-ethane to a quinonoid substance having the Jacobson formula; (2) partial dissociation of this compound into positive and negative ions in all solvents; (3) mutual interconvertibility of these ions by tautomeric change; and (4) the existence of the trivalent carbon atoms giving rise to free radicals," p. 303.

"We cannot say definitely that the ethylenic linkage is more or less active than the carbonyl bond; for the matter is influenced in different ways by the reagent employed, the solvent used, and the relative position of the two double bonds in the molecule. In other words, "unsaturation" is not a definite, measurable thing which we can predict in any case from the behaviour of the "unsaturated" substance in other circumstances; it is rather something kinetic, something which is extremely sensitive to external forces, and which in its turn can play a part in influencing the chemical action of groups which it does not apparently affect directly," p. 315.

"In the foregoing sections, no attempts has been made to include all the speculations which have been put forward from time to time with regard to the problem of benzene substitution. Instead, the aim has been to exhibit some of the very different aspects from which the matter can be regarded and in this way to bring out a number of points which stand in more or less close relationship to the main theme. When a problem is still unsolved, it is often quite as important to know what solutions have failed as it is to learn of those which have been partially successful; for in this way the waste of time involved in useless speculations along hopeless roads is avoided by those who wish to reconsider the problem *de novo* for themselves," p. 357.

"There is a second method of reading this history of organic chemistry; for we may take the career of a single investigator and endeavour to trace out how he passed from one line of research to another, and in this way try to put ourselves in his place and see how he was led on logically from problem to problem.

"As an illustration of this, the career of van't Hoff may be sketched in its bare outlines. In his student days, he evolved the idea of stereochemistry and extended the then existing structural chemistry into three dimensions. His next step is seen in his *Ansichten über die organische Chemie* where, amid the discussion of chemical structures, the idea of reaction velocities made its appearance. Three years later, this found a fuller expression in his *Etudes de dynamique chimique*; and the experimental work which was carried out by him in this field brought him face to face with the problem of chemical affinity. Here the affinity which unites the components of double salts attracted his attention and led to his discovery of transition temperatures. A second line of thought from the same starting-point brought him to consider the wider problem of solution and led to his enunciation of the osmotic pressure theory. And in his final completed research he again set out from this same jumping-off ground in order to elucidate the intricate problem of the oceanic salt deposits. From this it is easy to see that van't Hoff proceeded logically from one line of research to its successor; and that his ideas were all of that big and simple type which bear the mark of genius at work.

"Another example of the same kind may be drawn from part of Fischer's career. In an earlier chapter it has been shown how he developed the methods of synthesis in the field of the polypeptides, using the amino-group of one amino-acid to form an amide with the carboxyl group of another amino-acid molecule. At the conclusion of his investigation of the polypeptides he was led to examine a parallel series of reactions: the esterification of a hydroxyl-acid with the hydroxyl group of a second hydroxy-acid. In this way he came into the field of the depsides; and so he was led to approach the moss acids and tannin from the synthetic side. Thus the examination of one series of reactions drew him forward into fresh field, and this, in its turn, opened out into a completely new region of the subject," p. 365.

"The second volume is intended for Honours students and post-graduate workers. It contains a description of the latest work in several fields of interest in modern organic chemistry. In some of these the main work of clearing up the subject has been completed, whilst in others the problems are still unsolved, and all that could be done was to give some account of the present-day position," p. vi. The chapters are entitled: organic chemistry in the twentieth century; some carbohydrate constitutions; the sesquiterpene group; rubber; recent work on the alkaloids; the anthocyanins; the chlorophyll problem; the depsides; some theories of the natural syntheses of vital products; new organo-alkali compounds; other cases of abnormal valency; structural formulae and their failings; some applications of electronics to organic chemistry; some unsolved problems.

In the form in which it exists to-day, organic chemistry may be said to take its root in the work of Frankland at the middle of last century. Once the doctrine of the constancy of valency was accepted, the way was open for Couper and Kekulé to bring order into the vast mass of material which had been accumulated in earlier times; while, later, van't Hoff and LeBel carried the ideas of molecular arrangement out of two dimensions into three and laid the foundation of our present views. Following in the track of these pioneers, the chemists of the latter half of the nineteenth century rapidly developed the theoretical side of the subject; while, on the other hand, the modern formulae lent to synthetical work a certainty which had previously been unknown," p. 1.

"On the theoretical side of organic chemistry, to which we must now turn, Thiele's views on valency exerted a considerable influence during the century. It is very seldom that any theory is accepted immediately after being published; usually a considerable time is required during which the chemical world assimilates the author's views in a more or less unconscious manner, until some day they find their way into text-books. It is a remarkable tribute to the value of Thiele's partial valency theory that it became a classic almost as soon as it was published," p. 9.

"The most striking example of intramolecular change is the discovery by Hantzsch of a new class of electrolytes which have been named pseudo-acids and pseudo-bases. Previous to his work, the electrolytes known to us might be grouped under the four following heads: (1) Acids, which give rise to hydrogen ions; (2) Bases, which yield hydroxyl ions; (3) Salts, which dissociate into acidic and basic ions; and (4) Amphoteric electrolytes, which are capable of producing either hydrogen or hydroxyl ions according to the experimental conditions employed.

"Now when an acid solution is neutralized by means of a base, the solution is acidic at the beginning and remains acidic all through the titration until the neutralization-point is reached. On the other hand, if we start with a solution of nitromethane, it is neutral in reaction; and yet if we slowly add to it a solution of sodium hydroxide, the solution does not become alkaline at once. In fact, we may have to add a considerable quantity of alkali before the next drop produces an alkaline reaction in the liquid. Clearly nitromethane is a neutral substance which, *given time*, can exhibit acidic properties in presence of alkali. It is this *slow neutralization* which distinguishes it from a true acid," p. 10.

On p. 11 the author says that "the discovery of the pseudo-acids resulted in the collapse of Ostwald's hypothesis as to the nature of indicators." If the author had substituted the word "broadening" for the word "collapse," his statement would have been true. Ostwald said originally that an acid indicator is a weak acid whose ion has a different color from the undissociated acid. We now say that an acid indicator is a weak acid in which the ion or a product derived reversibly from it has a different color from the undissociated acid or a product derived reversibly from it. That change of wording may mean collapse to an organic chemist; but most chemists have sturdier constitutions.

"In the whole field of stereochemistry, no more puzzling phenomena are known than those grouped under the head of the Walden Inversion; and at the present day we still await a solution of the problem. The data are so complicated that it could be impossible to deal with them fully here: all that can be done is to indicate the nature of the question," p. 16.

"We now come to a subject which lies in the borderland between organic and physical chemistry, namely the relations between the physical properties of compounds and their chemical structure. The problems comprised in this branch have for the most part, been solved by organic chemists, owing to the fact that the material of experiment is largely drawn from the carbon compounds. The curious step-motherly fashion in which this important subject has been treated by the ordinary physical chemist is possibly due to the influence of Ostwald who had a large following among the older group of physical chemists; or it may be ascribed to the fact that few physical chemists have any claim to be ranked as even moderate organic chemists, a fact which handicaps them in this particular line of research. Whatever be the reason, there is no doubt that the relations between chemical constitution and physical properties so fully recognized by van't Hoff, have not been pursued with either eagerness or success by the physical chemists of the Ostwald School," p. 22.

"It is well known to every chemist that when dextro-rotatory cane-sugar (sucrose) is hydrolysed with dilute acids, the resulting mixture of glucose and fructose is laevo-rotatory, whence is derived the term "inversion" to describe the process. The origin of the change in rotatory power is found in the fact that the dextro-rotatory sucrose molecule is split up into a dextro-rotatory glucose molecule and a laevo-rotatory fructose molecule of much higher rotatory power. The result of this is that the mixture possesses laevo-rotation. Now when sucrose is methylated and hydrolysed, the octamethyl-sucrose splits up into tetramethyl-glucose and tetramethyl-fructose; but *no inversion of the sign of the rotatory power is observed*. This apparent anomaly is due to the fact that the methylated fructose residue differs from ordinary fructose in being strongly dextro-rotatory instead of showing laevo-rotation. This furnishes conclusive proof that the fructose molecule is capable of existing in two different forms. As combined in the sucrose molecule, it is in the γ -form; and during the inversion of sugar it reverts to the normal stable fructose type. If this intramolecular rearrangement is prevented by methylation, which lacks the molecular structure, then the product of inversion is the tetramethyl-derivative of the γ -form and not a

derivative of the normal form. This conception of the matter is reinforced by the fact that tetramethyl fructose derived from the methylation of methyl-fructoside differs greatly in physical and chemical character from the tetramethyl-fructose obtained from octamethyl-sucrose. The former compound is stable towards permanganate, the sucrose product is unstable in presence of permanganate; and the two substances present the contrast in rotatory power which was referred to above," p. 46.

"In actual practice, the hydrolysis of cellulose is hemmed in by difficulties. From time to time accounts have appeared in the literature describing how practically quantitative yields of glucose have thus been obtained; but these have been adversely criticized by Irvine and Soutar. These two investigators carried out careful investigations in which only actually isolated glucose was taken into account; and they were able to prove that the glucose yield from cellulose on this basis was a minimum of 85 per cent., which compares very favourably with the normal yields of reactions in the sugar group, since these rarely reach 80 per cent. Later, Monier-Williams recorded a yield of 90.67 per cent. of the theoretical quantity, his result also being based on actually-isolated glucose. Finally, Irvine and Hirst obtained an over-all yield of hexose from cellulose amounting to no less than 95.1 per cent. of the theory. From these figures it seems not unwarranted to suppose that cotton cellulose is essentially composed of glucose units," p. 70.

"The Röntgen diagrams of cellulose hydrate, oxycellulose (derived from oxidation of viscose), and hydrocellulose (prepared by the reduction of viscose), have been found identical with the diagram for lichenin, which shows that all these materials have the same crystalline constituents. This evidence suggests that cellulose and lichenin are both built up from basal units which have the character of glucose anhydrides," p. 75.

Zingiberene sounds like an Edward Lear word; but it seems to be a sesquiterpene found in ginger oil, p. 103. The author says, p. 117, that "this work of Tilden's should be regarded as a real synthesis of rubber, and stands in a different category from Bouchardat's. Bouchardat obtained his isoprene by distilling rubber; so that his work consisted of *re-synthesising* rubber from its decomposition products. Tilden, on the other hand, obtained his isoprene from turpentine, and may thus claim to have made a true synthesis of rubber." This seems very far-fetched. Both men condensed isoprene to a rubber. The source of the isoprene would be a very important matter if this were a commercial problem; but it is quite immaterial so far as the scientific side of the question is concerned. There was no reason to suppose that the source of the isoprene affected its reaction seriously. It is so easy to carry partisanship too far.

The author does not accept the view of Harries, p. 119, that isoprene rubber is dimethyl octadiene.

"Ostromisslenski differed from Harries with regard to the classification of the rubber-like materials produced by synthetic methods. In his view, the physical properties of the product are better indices of its nature than the results of decomposition reactions have proved to be. For example, a determination may be made of the temperatures at which an artificial rubber acquires and loses its elastic properties; and if these temperatures agree approximately with those for natural rubber, Ostromisslenski considered that the synthetic substance is "normal." If, on the other hand, there is little agreement here and if the range of temperature over which the artificial product remains elastic is different from the range found for natural rubber, then the artificial product should be regarded as abnormal," p. 129.

"The isomerism of codeine and pseudocodeine therefore arises from the fact that the $-\text{CH}(\text{OH})$ -group occupies the position 6 in one molecule and the position 8 in the other. These reactions enable us to compare the formulae [for morphine] of Collie and Pschorr. The Collie formula agrees with the facts; whereas in the Pschorr formula the position 8 is already occupied by the isoquinoline ring. From this it is evident that Collie's formula is the more correct of the two," p. 166.

"The solvent chosen for the removal of the pigment from the petals of flowers or the skins of berries varies, of course, according to the nature of the anthocyanin present. In the case of the cornflower, water alone suffices to dissolve the colouring material; hydrochloric

acid in methyl alcohol solution is used in the cases of the rose, the hollyhock, the mallow, the peony, and the bilberry; dilute alcohol is employed to remove the pigments from the larkspur and the scarlet pelargonium; whilst acetic acid is found to be the best solvent in the cases of the grape and whortleberry," p. 174.

"The importance of metallic derivatives of the anthocyanins has been emphasized by some work on the subject. Reduction of a flavone derivative by means of a metal and a *mineral* acid leads to a production of a red compound; but when magnetism and an *organic* acid such as acetic acid is employed in presence of mercury, the colour of the product is found to diverge from the normal red tint. . . The difference between the reaction products when mineral and organic acids are employed has been traced to the fact that the radicle — Mg.Cl is replaced by a chlorine atom if hydrochloric acid is present in quantity; so that the end-product is the red oxonium chloride," p. 186.

"Basing themselves upon these result, Shibata, Shibata and Kasiwagi suggested that metallic complex salts of this type are important factors in flower coloration and give rise to the "blue" anthocyanins. The metallic atoms which they contain are probably calcium and magnesium. The "violet" and "red" pigments are assumed to be complex salts containing fewer hydroxyl groups than the "blue" ones; or to be mixtures of the "blue" compounds with a certain quantity of red oxonium salts which have been formed from the "blue" derivatives by decomposition with acids.

"The existence of these various types would be conditioned by the nature of the sap in the neighborhood of the pigment; and as the sap must obviously be more highly concentrated the nearer we go to the evaporating surface of the petals, it is evident that variations in the structure of the pigment must be expected. Again, the sap in certain parts of the plant may be more alkaline than in others; and as the cyanidins are indicators, it is clear that their tint will be affected by this factor also," p. 187.

"In the higher branches of the vegetable kingdom, chlorophyll plays a most important part in the vital economy of the organism; whilst in animals an equally essential factor is the colouring matter of the blood. The parallel functions of the two compounds suggest that some similarity in nature might be traced between chlorophyll and haemin; and a survey of the chlorophyll problem would be incomplete without a brief reference to the colouring material of blood.

"Examination of the blood pigment shows that it is composed of two portions; an albuminous substance called globin and a non-albuminous compound named haematin. It is with the latter that we are here concerned.

"Both chlorophyll and haematin are metallic derivatives, the magnesium of chlorophyll finding its analogue in the iron of haematin. In each case the metallic atom displays an abnormal character; and both compounds can be freed from their metallic portion by similar treatment. Finally, when analogous degradation methods are employed in the two cases, aetioporphorin is produced from both chlorophyll and haematin. These facts are sufficient to justify the assumption that the two substances are related to one another in a more than superficial degree," p. 204.

"Up to the present time the lichens are the solitary abundant natural source of depsides. If Schwendener's views be correct, the lichens are produced by a symbiosis of fungi and algae; and possibly this peculiar origin may account for the presence in their tissues of the depside group, which is so conspicuously scarce in the rest of nature," p. 220.

"How does it come about that the depsides occur so plentifully in one particular type of plant-life? The rarity of the depsides in general, as compared with the profusion of the proteins in nature, can perhaps be accounted for on lines already suggested on an earlier page. Amide-formation depends upon the combination of dissimilar groups, whilst in the esterification of a phenolic acid two groups of a much less unlike character are being linked together. But this serves only to make the case of the natural depsides still more strange; for it is difficult to see why, when they do occur, the plant should produce such relatively enormous yields as are indicated by the high percentage of tannin in galls. Nor does it account for the limitation of the sources of the natural depsides. In this last connection, one point may be suggestive. Every one knows that mosses grow best in dimly-lit localities;

whereas the ordinary plant flourishes only in a good light. Now the normal plant is engaged in building up cellulose, whereas the moss synthesizes a large proportion of depside which is not found in the normal vegetable. Is it beyond the bounds of possibility that there is some connection between these facts; and that photochemical action plays its part in the problem," p. 333?

"All reactions which are likely to be employed in vital syntheses are reversible; and hence if they be carried out in glass test-tubes they must come to an equilibrium point, except in those cases wherein gaseous products are formed. How, then, does the plant succeed in producing its high yields of certain substances which, in a test-tube, would be formed only in minor quantities from the same reagents? When we examine the living plant, we are at once struck by the wonderful mechanism of the natural chemical laboratory which we find there. It is a system of test-tubes made of cellulose and differing from ordinary test-tubes in that the walls are constructed from semi-permeable membranes. Each cellulose test-tube is immersed in a solution differing from that which is contained within the cellulose vessel. The membrane acts not only as a container, as the glass test-tube does, but in addition it behaves as a filter, a concentrator, or a separator. Thus during the progress of a down-grade reaction in which a complex molecule is broken up into constituent parts, the cellulose wall permits a certain product to accumulate in one part of the plant whilst a mixture of other compounds may be withdrawn to a different region. In this way the ordinary equilibrium stage of the reaction is evaded; and much higher yields may thus be attained," p. 237.

"Photochemical effects must, of course, play a very striking part in vital processes, especially in the vegetable kingdom. Of these, the most important from the theoretical standpoint is the discovery by Cotton that the dextro- and laevo- forms of tartaric acid absorb *d*-circularly polarized light to different extents; which implies that such light will decompose them at different rates. Now since light is circularly polarized by the surface of the sea, we have a natural method whereby the production of unequal quantities of asymmetric material can be attained; and once the balance between the two isomers is thus disturbed, the general production of optically active compounds becomes possible. It may be that these experiments indicate the manner in which optically active substances first made their appearance on the earth's surface," p. 246.

"The fatty acids of the acetic series are quite common in nature, whilst their hydroxyl-derivatives—with the exception of lactic acid—are hardly represented at all. Why should this be so? Why do all the important sugars and starches contain a chain of five or six or a multiple of five or six carbon atoms? Why are the majority of the amino-acids obtained from the proteins the α -amino-acids? Why are the ortho- and meta-derivatives so strongly represented among naturally occurring benzene derivatives, whilst the majority of the terpenes are derived from *para*-cymene?

"In the case of such broad generalities there must surely be some simple solution. The curious thing is—not that the answers to these questions are omitted from the ordinary text-books, but rather that the questions do not appear to have suggested themselves to the writers at all," p. 276.

"The abnormal compounds described in the present chapter, as well as their allies among the metal-ketys and the triphenyl-methyl series, cannot fail to suggest problems affecting the very bases of structural chemistry. Once the conception of free radicals is admitted, the long-tried dogma of the quadrivalence of carbon comes into the scales for a final test. It is doubtful if all the older ideas will be suddenly thrown aside. Much more probably we shall simply incorporate the idea of free radicals in our thinking and shall not trouble ourselves too much over the incompleteness of our valency scheme. But the chemistry of free radicals, as it extends, is certain to have a marked influence upon our ultimate conception of valency. During the present generation, there has been a gradual process of facing fresh facts with regard to the chemical bonds, so far as organic chemistry is concerned. This first manifested itself in a preoccupation with residual affinity and partial valencies; then it showed itself in the attempt to bring electronic ideas to bear upon the carbon compounds; and finally, in recent times, the atomic theory of G. N. Lewis seems to

have given us something much more definite and satisfactory than anything which preceded it. It is much too soon, as yet, to consider ourselves on firm ground; but when the further implications of the Lewis theory have been worked out and applied to unsaturated compounds in general, it seems not unlikely that we shall have a much clearer idea of a good many problems than we have at present.

"The case of the free radicles is of special interest from the standpoint of Lewis's theory, since in the triphenylmethyl derivatives carbon acts as an ionogenic element, and thus we have a bridge built between that behaviour of the normal non-ionogenic carbon derivatives on the one hand and the ionizable molecules of salts upon the other hand. Lewis's theory, with its conclusive sweep, seems to offer most interesting possibilities in this region of chemistry," p. 317.

"Intramolecular change furnishes one of the most interesting fields for speculation in organic chemistry. Two problems are evidently involved in the question: for we may inquire, in the first place, why one particular structure is more stable than an isomeric form; or, secondly, we may endeavour to conjecture the mechanism of the process whereby the one isomer is converted into the other. Let us take certain well-known examples of intramolecular changes and see if they can be accounted for by any general principle. It will be sufficient if we examine the pinacone change, the Beckmann rearrangement, the benzoic acid change, and the hydrobenzoin change," p. 359.

The author has a real talent for this sort of thing and it is to be hoped that he will write many more books. There are not many people who can do it and the talents of the few should not be wasted.

Wilder D. Bancroft

A Text-Book of Inorganic Chemistry. Vol. VII, Part I. Edited by J. N. Friend and D. F. Twiss. 23 X 16 cm; pp. xxvii + 370. London and Philadelphia: Charles Griffin and Company, J. B. Lippincott Company, 1924. Price: \$7.50. This part of the volume deals with oxygen. The chapters are entitled: general characteristics of the elements of Group VI; oxygen; the physical properties of oxygen; the chemical properties of oxygen; ozone; the atmosphere; water; physical properties of water; chemical properties of water; composition and molecular complexity of water; water as a solvent—water analysis; hydrogen peroxide.

"The commercial commodity known as "oxylithe" has the following composition: sodium peroxide, 98.32; oxide of iron, 1.00; copper sulphate, 0.68," p. 17.

"The most probable explanation is that alternately higher and lower oxides of manganese are formed—the higher oxide by the oxidising action of the heated chlorate, and the lower oxide by the decomposition of the higher, either alone or in contact with a further supply of chlorate. Mention has already been made of the fact that, when potassium chlorate is heated alone, some perchlorate is formed through self-oxidation simultaneously with the evolution of oxygen. This reaction does not occur in the presence of manganese dioxide, since this oxide effects the decomposition of the chlorate into chloride and oxygen at a temperature considerably below that at which autoxidation of the chlorate proceeds at an appreciable rate," p. 22.

"The theory that the catalyst effects the decomposition [of bleaching powder] by its own alternate oxidation and reduction is supported by the result of passing chlorine into a 50 per cent. solution of sodium hydroxide containing dissolved copper hydroxide; the blue solution at first deposits a yellow copper peroxide, which rapidly decomposes, evolving oxygen and regenerating the original solution. The effect of adding two catalysts to bleaching powder is remarkable. If the bleaching powder is made into a cream with water, oxygen may be liberated at the ordinary temperature by addition of a ferrous or manganese salt and in the presence of a copper or nickel compound. The best result is obtained with a mixture of ferrous and copper sulphates," p. 23.

"Plumbosan, a mixture of the manganate and meta-plumbate of sodium, namely, $\text{Na}_2\text{MnO}_4 \cdot \text{Na}_2\text{PbO}_3$, readily evolves oxygen when heated, in a current of steam at 430° to

450° C. The plumbosan is regenerated at the same temperature by replacing the steam with air, the issuing gas, during the initial stages of regeneration, consisting of a fairly pure nitrogen.

"The oxygen obtained by this process is very pure if the precaution is taken to remove the last traces of nitrogen from the pores of the plumbosan after regeneration by connecting to a vacuous vessel before introducing the steam. The chemical reactions taking place are very complex, and but imperfectly understood," p. 26.

When speaking about the assimilation of carbon dioxide by plants under the influence of sunlight, the authors say, p. 27, that "the energy necessary for this reaction, which is endothermic, is obtained from the light, the most active rays being, curiously enough, those of the red, orange, and yellow portions of the spectrum, and not the chemically reactive rays of the blue and violet end." Everybody else considers this as absolutely normal, because the blue and violet rays are not absorbed strongly.

In the production of liquid air by the Claude process, "the difficulty of lubrication appears to have been mainly responsible for the failure of previous attempts, and this was first overcome by the employment of petroleum ether which does not solidify, but merely becomes viscous at such low temperatures as -140° to -160° C. Later, however, it was found that leather retains its ordinary properties at these low temperatures, and in 1912 leather stampings were fitted to the working parts of the machinery to the entire exclusion of lubricants," p. 28.

"Oxygen is also soluble in certain molten metals, *e.g.* platinum and silver, more than twenty times its own volume of the gas being absorbed in the case of the latter metal; the dissolved gas is largely, but not completely, restored at the moment of solidification of the metal, and the phenomenon of "spitting" is thus produced. The power of oxygen to diffuse through heated silver, whereas glass is impervious, is probably due to this solubility of oxygen in the metal," p. 43.

"The rate of oxidation of any particular substance is dependent upon various factors, to wit, its own physical condition as well as that of the oxygen; the presence of moisture or of a catalyser; and the application of light, heat, and pressure. Thus, liquid oxygen does not affect phosphorus or the alkali metals; neither does it combine with solid nitric oxide, although a small jet of burning hydrogen will continue to burn below the surface of liquid oxygen, the water produced being removed as ice and a considerable amount of ozone being formed. Similarly graphite and diamond, when once ignited, will burn on the surface of liquid oxygen, the carbon dioxide produced being frozen and some ozone passing into solution," p. 50.

The author says, p. 52, that "by flame is generally understood a mass of gas raised to incandescence," forgetting that it is practically impossible to heat a transparent gas to incandescence. "It is possible to prepare an active form of oxygen analogous to active nitrogen by subjecting the dry, ozone-free gas to the influence of an electric discharge. It yields a weak, bluish-green afterglow, which is less persistent than that of hydrogen. When mixed with active nitrogen, this active oxygen yields oxides of nitrogen. Both oxygen and ozone are unaffected by active nitrogen. Hence active oxygen is different from these, but is capable of existing for only a short time," p. 52.

After discussing slow oxidation, the authors say, p. 56, that "probably all these theories possess an element of truth; against each of them some objection may be raised; there is yet room for some comprehensive explanation which shall remove all difficulties."

"There has been discovered in the tissues of animals and plants a class of complex organic compounds, termed *ferments* or *enzymes*, which are capable of exerting marked catalytic action on certain chemical reactions. Some of these substances are catalytically active in fermentation processes by the atmosphere, and these bodies are frequently distinguished towards *oxidation oxydases*. Oxydases are widely distributed and the discoloration of the guished by the use of some fruit is to be referred to atmospheric oxidation induced or freshly broken surface. Colcholic tincture of guaiacum resin in the presence of an oxydase aided by an oxydase. An oxygen with formation of a blue coloration, and so provides a undergoes oxidation by free oxygen of this type of substance. Manganese, and also convenient reagent for the identification.

iron, compounds, are frequently present in these oxydases, and it appears probable that in some cases one of these metals, if not both, actually plays an important part in the catalytic process. In some cases, however, compounds of these metals are absent, so that in such oxydases the activating effect appears to be characteristic of the organic enzyme itself," p. 58.

"When a mixture of oxidisable substances is so treated that certain of the constituents only are oxidised to the more or less complete exclusion of the remainder, the process is known as selective oxidation. In cases of gaseous combustible mixtures, the passage over catalyst frequently effects the selective combustion of one constituent. Thus, for example, when a mixture of oxygen, hydrogen, carbon monoxide, methane, and nitrogen is passed over spongy platinum at 177°C. the hydrogen and carbon monoxide are oxidised, but not the methane. This is termed selective oxidation, and is the basis of Hempel's method of analysing certain gaseous mixtures. The selective oxidation of carbon monoxide in excess of hydrogen by passage over catalysts at suitable temperatures has been studied by Rideal, who shows that the oxide of copper (operative at 110°C.) and the oxides of iron and chromium (operative at 250° to 350°C.) are active in inducing the oxidation of the monoxide, although in no case is the selective oxidation complete," p. 59.

"Had Europe possessed an Arctic climate with a maximum temperature below 7°C., it is possible that the discovery of phosphorescence of phosphorus might have been long delayed. Upon ignition with a lighted taper the phosphorescent temperature interval would have been passed so rapidly that the phenomenon would not ordinarily be observed," p. 61.

"It has long been known that certain flames are capable of existence at relatively low temperatures. Thus, a century ago, Davy observed that when a hot platinum wire was introduced into a mixture of ether vapour and air, not only did the wire become red hot in consequence of active surface combustion, but a pale phosphorescent light could be detected above the wire, particularly when the latter ceased to glow, if the experiment were conducted in a dark room. Doebereiner observed the same phenomenon, and mentioned that when ether is dropped into a retort at 100°C. it may assume the spheroidal state accompanied by a pale blue flame, visible only in the dark, and too cool to set fire to other bodies. Perkin suggests several ways by which this phenomenon may be exhibited at lectures. Of these, perhaps the best is to heat an iron or copper ball to dull redness, allow it to cool to such a temperature that it is just invisible in the dark, and, by means of a wire, suspend it over a dish containing several filter papers saturated with ether. As the ball approaches the ether, a beautiful blue flame will form, passing over its heated surface upwards for several inches. The ball may be let right down into the ether without causing ordinary combustion. The blue flame is characterised by its low temperature. The fingers may be placed in it without discomfort; paper is not charred by it, and even carbon disulphide is not ignited by it," p. 76.

"In 1815 Davy suggested that the luminosity of a candle flame is due to the presence of minute particles of carbon at white heat. These particles were believed to be produced by incomplete combustion of the hydrocarbon vapours in the restricted supplies of air available within the flame, the hydrogen of the vapours being "preferentially" oxidized, leaving the carbon to shift for itself. This theory was generally accepted for many years, and it was not until 1867 that a rival theory was projected by Frankland, according to which the luminosity of the flame is due to radiations from dense but transparent hydrocarbon vapours," p. 78.

"From the foregoing it will be evident that a decision between the theories of Davy and Frankland cannot be easily arrived at. Indeed, it is by no means impossible that both theories are correct in so far as they go. The only really certain feature is that the luminous zone is diphasic," p. 79. This is rather hopeless because an oxyhydrogen flame, for instance, is not diphasic. What the authors have overlooked is that there are two independent sources of luminosity in a flame, the incandescence of solid particles, which is a thermal luminescence, and a true chemiluminescence. The problem is quite simple if it is once formulated properly. Davy was right for thermal luminescence; but his view-point does not account for the colors of salt flames. It is not true to say, as the authors do on p. 81

that "the higher the temperature of a flame, the greater will become its luminosity, the change being due to a general shortening of the wave-length of the radiation." This is true only for the case of thermal luminescence.

"By lowering the temperature it is possible greatly to increase the yield of ozone which, under ordinary conditions, is less than 10 per cent. of the oxygen. By immersing an ozonising apparatus in a cooling mixture of ether and solid carbon dioxide and so working at $-78^{\circ}\text{C}.$, a yield of 11 per cent. has been obtained, whereas in liquid air it was found possible to convert 99 per cent. of the oxygen into ozone, the best results being obtained at this temperature with a pressure of 100 mm., the oxone liquefying out as it is formed," p. 141.

"Obtained in this way, ozone may be purified by fractional distillation at low temperatures, the boiling-point of ozone being some 63° above that of oxygen. The ozonized oxygen liquefied by cooling in liquid air. The deep-blue liquid thus obtained evolves mainly oxygen under reduced pressure and at a certain composition separates into two layers. The upper, dark-blue layer consists of a solution of ozone in liquid oxygen; the lower deep violet-black layer is a solution of oxygen in ozone and contains, at $-183^{\circ}\text{C}.$, some 30 per cent. of oxygen. All but mere traces of oxygen are removed in a single fractionation of this liquid, and by careful manipulation pure ozone, B.P. $-112.4^{\circ}\text{C}.$, may be obtained," p. 142.

"Carbon tetrachloride dissolves approximately seven times as much ozone as does water, and when oxygen containing six percent of ozone is passed through the former solvent a distinctly blue solution is easily obtained," p. 146.

"When ordinary ozone is allowed to react with unsaturated organic compounds, the element is sometimes taken up by the latter in groups of four atoms instead of the usual triatomic groups, whereas if the ozone is previously washed by passage through sodium hydroxide solution and sulphuric acid, the addition occurs only by groups of three oxygen atoms. The formation of oxozonides, as Harries terms the products containing O_4 groups, is attributed by Harries to the presence of oxozone O_4 in the crude ozone. The evidence as to the possible existence of a tetratomic form of oxygen, however, cannot yet be considered as satisfactory. Vapour density determinations reveal no tendency on the part of even pure ozone to associate to higher complexes than that corresponding to O_3 ," p. 152. Recent determinations of the vapor density of pure ozone confirm the value 48 for the molecular weight. No tendency to associate to higher molecules has been observed either in the pure liquid or that gas," p. 155.

"As a general rule any harmful effect produced on man by air must be due to some foreign impurity in the air; the mixture of nitrogen and oxygen is an absolute necessity for prolonged existence. The fat of mammals, however, dissolves more than five times as much nitrogen as does an equal amount of water, and this fact may give rise to serious results with men working under conditions, for example, in caissons, in which the external atmospheric pressure undergoes sudden and considerable variations. If the reduction in pressure is too sudden the fat-containing tissues of the workers are liable to injury on account of the formation of gas bubbles," p. 159.

"Not merely does the proportion of oxygen [in the atmosphere] vary from place to place; but it also varies at one and the same place from time to time. Thus Levy found that the air of New Granada underwent remarkable changes, after great forest conflagrations, the oxygen content falling from 21.01 to 20.33 percent. Such a variation is decidedly abnormal, but in volcanic districts is perhaps more frequent than is generally known," p. 163.

"Considerable variation [in the amount of carbon dioxide] may be due to local circumstances. Thus Reiset found that the presence of a flock of 300 sheep on a fine, calm day in Dieppe induced a notable rise if the proportion of carbon dioxide in the immediate neighborhood, which registered 3.18 parts per 10,000 instead of 2.96—the normal value for Dieppe. The influence of vegetation upon the carbon dioxide content of the air has not received the consideration it deserves, although a few isolated experiments have been carried out. Ebermayer, for example, found an excess of the gas in the forest, a result that confirmed the earlier observations of Truchot. In confined spaces, such as dwellings, the carbon dioxide shows a marked increase owing to its being a product of human metabolism, and may reach 0.5 per cent.," p. 167.

"From the point of view of ventilation, ozone and peroxides are of interest as they impart a crispness or freshness to the air, and the fact that they are readily decomposed by heat is probably one of the causes of the "flatness" of heated air. The well-known Sanitas preparations are essentially solutions of hydrogen peroxide and of different organic peroxides. There can be no doubt that in nature the presence of hydrogen peroxide is an important factor in removing foetid and putrid matter from the atmosphere. Bosisto has calculated that 96,877,440,000 gallons of eucalyptus oil are held continually at one and the same moment in the leaves of trees massed together and occupying a belt of country over which the hot winds blow in New South Wales and South Australia alone. Kingzett concludes that this amount of eucalyptus oil can and must produce in the atmosphere surrounding the forests no less than 92,785,023 tons of peroxide of hydrogen, and about 507,587,945 tons of the soluble camphor, not to mention the other products of oxidation," p. 177.

"It is interesting to recall the experiments of Lehmann and his colleagues who demonstrated quite recently that when a dust-laden air is breathed through the nose, approximately 40 per cent. of the dust remains in the system, either in the lungs or stomach, the remaining 60 per cent being either respired or retained by the nose and mouth. If, however, the subject breathes through the mouth some 80 per cent is retained by the body. This illustrates the importance of breathing through the nose, but it also illustrates the necessity of reducing the dust in the atmosphere of public rooms and dwellings to the smallest possible amount, as no matter how careful a subject is, some of the dust finds its way into the system," p. 184.

"The presence of moisture in air has a two-fold action upon respiration. First, there is the very obvious fact that if warm air saturated with moisture enters the lungs, the latter will have great difficulty in discharging their superfluous moisture, and a sense of oppression must result. This explains the heavy feeling produced upon entering hot-houses, in which the air, apart from its moisture content, is perfectly good, and very free from carbon dioxide. Cold air, even if saturated with moisture, will not have anything like the same effect, for upon entering the lungs the temperature rises proportionately higher, and the air is thus able to take up much more moisture before becoming saturated, thereby allowing the lungs full opportunity to relieve themselves. Secondly, air containing moisture cannot take up carbon dioxide from the blood as easily as dried air, consequently the ventilation of the lungs is retarded by inhaling moist air.

"These two factors working together are sufficient to show that respired air, being saturated with moisture at a warm temperature, cannot be wholesome, and L. E. Hill and his co-workers regard the moisture content as the main cause of the discomfort of ill-ventilated buildings," p. 186.

"Spring water, particularly that derived from deep-seated springs, is usually beautifully clear and sparkling. The clearness is mainly due to thorough filtering during percolation through the soil, whilst the sparkle is caused by the presence of gases, mainly carbon dioxide, in solution," p. 206. Waters containing hydrogen sulphide "have been used frequently in by-gone days for secret correspondence. Letters written with a solution of lead acetate become legible when dipped, for example, in Harrogate water," p. 209.

"Ferruginous water are bitter to the taste, even one part of iron per million of water being perceptible to the average individual. Such waters, which are widely distributed in Germany and the Netherlands, in America, and elsewhere, are particularly favourable to the growth of minute organisms, such, for example, as the *Crenothrix*, the vitality of which appears to be connected with the secretion of iron within the tissue of its cell walls. This organism flourishes in waters containing 0.3 parts of iron per million of water, and may lead to serious choking of water-mains. Aeration and treatment with lime or with colloidal substances have been adopted with more or less success. Thus, for example, at Amsterdam, intense aeration followed by filtration has reduced the iron content of its water supply from 0.8 parts per million to *nil*. Iron may also be completely removed from water by passage through a manganese permutit filter," p. 234.

"A very striking instance of the value of sand filtration was afforded by the outbreak of cholera in Hamburg in 1892. The city drew its water from the Elbe and used it in its raw

condition for domestic purposes. No fewer than 1250 per 100,000 of the population perished through cholera. The contiguous town of Altona lost but 221 per 100,000 despite the fact that it drew its domestic water from the Elbe below Hamburg, after it had received the sewage pollution from the latter city. This relative immunity was due to the fact that the Altona authorities purified their water by passage through sand filters," p. 235.

"Although the compressibilities of natural waters are exceedingly small, their effect upon the distribution of land and water on the crust of the earth is important. It has been calculated that, in consequence of the compressibility of sea-water, the mean sea-level is 116 feet lower than it would be if water were absolutely incompressible, with the result that two million square miles of land are now uncovered which would otherwise be submerged," p. 264.

"It is interesting to note that whereas ice produced with a cooling temperature within one or two degrees of the melting-point is usually clear, the product obtained with stronger cooling is milky in appearance on account of the inclusion of minute bubbles of air which was previously in solution."

"Livingston mentions that the temperature of the surface water of ponds in the central regions of Southern Africa may reach as high as 38°C., but, owing to the poor conductivity of heat, deliciously cool water may be obtained by anyone walking into the middle and lifting up the water from the bottom," p. 270.

On p. 345 the authors say that "it is interesting to note that, whilst solutions of aniline green and of magenta are not bleached by dilute hydrogen peroxide solution in the dark, yet upon exposure to the light of a quartz-mercury lamp the colours fade readily. It would appear, therefore, that, under the influence of the light, the peroxide becomes increasingly active." While this conclusion may be right it is not necessary. The dye may have been activated by the light.

Wilder D. Bancroft

Erratum

A number of errors have occurred in the proof-reading of the article by Messrs. Swan and Urquhart entitled "Adsorption Equations" (31, 251). The references to Williams under "The Isobar: Theoretical" on pp. 251, 267 should be deleted. In the papers of Williams there referred to, no equation is given for the isobar nor is any derivable from his isostere equation. On p. 253 change the equation at the bottom of the page to $\log \lambda_t = \log \lambda_o - \theta \log (a/v)$.

On p. 254 change to $(a/v)_\theta = (a/v)_o - \zeta^\theta$.

On p. 256 change to $\mu = p/\sqrt{2\pi MRT}$

On p. 257 change to $\eta = (N_o/2N)\sqrt{k/m}$, to $\eta \propto p^{1/2}$, and to $C = 2k_2(6k_2k_3 - 2k_2k_4 + k_1k_2 - k_1k_3 - 4k_2^2)$.

On p. 258 change to $X = OC_\infty \int_0^\infty (e^{-Fh/RT} - 1) dh$.

On p. 259 change to $X = \frac{O\delta C_\infty e^{k/T}}{2\mu (k/T)^2}$

On p. 263 change to $\frac{d \log \lambda}{d \log c} = \frac{d \log x}{d \log c} - \frac{1}{\log c_o/c} + \frac{c/c_o}{1 - c/c_o}$

On p. 264 change to curve 2, Fig. 2.

On p. 267 change to $\log x_\theta = \log x_o - (\zeta - \xi \log p) \theta$, to $\zeta = -dk_\theta/k_\theta d\theta$, and to $\log p_\theta = \log p_o - \xi \theta$.

On p. 269 change to $y = A\alpha^t \pm B$, $y = A\alpha^t$, or $y = A\alpha^t \pm B\beta^t$, and to " α and β are constants."

On p. 270 change to $k = \frac{1}{t(a - x_\infty)} \left(\log \frac{a - x}{x_\infty - x} \cdot \frac{x_\infty}{a} \right)$

On p. 271 change to dx_r/dt .

On p. 275 change reference 55 to Langmuir: J. Am. Chem. Soc., 38, 2221 (1916).

STUDIES IN DYEING

BY ROBERT C. HOUCK

SILKS AND DYESTUFFS

Introduction

In dyeing silk with colors not necessarily fast to light and washing, both acid and basic dyes are used. The basic colors are especially adapted to silk because of the clear brilliant tones of pure colors obtained with them. In both cases, dyeing is carried out in a boiled-off liquor bath. The action of the boiled-off liquor or bast soap on the process of dyeing and the effect of addition agents are studied in this thesis.

In black silk dyeing the various coal-tar black dyes have generally a slaty faded appearance. This is due to the fibre being so translucent that the full black color is diluted with an excess of transmitted light. To obtain a good black on silk the fibre must be rendered opaque. Logwood accomplishes this purpose and is used in connection with a tannin mordant. A study is made of the adsorption of tannin by silk in view of this.

In consequence of the unexpected behavior of tannin with silk at different temperatures, it was thought desirable to make a few experiments on the precipitation of tannin by acids, especially in view of the work of Thomas on the precipitation of tannin extracts. It was thought possible that a pure tannin might precipitate pretty sharply at a given degree of acidity; but this proved not to be the case.

Addition Agents in the Dyeing of Silk with Acid and Basic Dyes

Numerous theories have been formulated to explain the process of dyeing. Briggs and Bull¹ have shown conclusively that in the dyeing of wool the taking up of acid and basic dyes is a case of adsorption.

The adsorption theory has been summarized at length by Bancroft.² With acid dyes the theory is as follows. In the presence of a solution a fibre tends to adsorb everything in the solution varying with the nature, concentration, and temperature of the solution and with the nature of the fibre itself. With an acid dye in acid solution the constituents of the dye-bath would be hydrogen ions, sodium ions if the dye were a sodium salt, dye anions, acid anions, and undissociated compounds. The hydrogen ions being more strongly adsorbed as a rule than any of the other univalent cations present, and the dye anions being adsorbed more strongly for the same concentration than the other anions, the free dye acid is what is adsorbed normally.³ The dye anions have to compete with the other anions and therefore the addition of strongly

¹ J. Phys. Chem., **26**, 845 (1922)

² J. Phys. Chem., **18**, 1, 18, 385 (1914); **19**, 50, 145 (1915).

³ Bancroft: J. Phys. Chem., **18**, 10 (1914); "Applied Colloid Chemistry," 115 (1921).

adsorbed anions will cut down the amount of dye taken up by the fibre while the addition of strongly adsorbed cations will increase the amount of dye taken up. A high concentration of hydrogen ions will therefore increase the adsorption of acid radicals. This means that acid dyes will be taken up most readily in acid solution; but that they may be taken up in neutral or alkaline solution. Sulphuric acid will cause less of an acid dye to be taken up than an addition of an equivalent amount of hydrochloric acid or than the addition of isohydric hydrochloric acid. The addition of sodium sulphate to the bath will cut down the adsorption of an acid dye and will cause more even dyeing.

The effect of the addition of any definite reagent¹ to the dye-bath may be the result of several factors. It may affect either the fibre or the dye-bath. The reagent added may either act chemically on the fibre or be adsorbed and in so doing change the adsorption of the other substances present in the bath.

With the dye-bath the effect may be more complicated. The reagent may react chemically with the dye as in the case of Crystal Violet and potassium hydroxide, giving in this instance a white insoluble leuco base. If the dye is in true solution it might change the solubility of the dye and thus change the amount adsorbed. If the dye is in colloidal solution it might affect the degree of dispersion and alter the amount taken up. The reagent may also change the hydrogen ion concentration. This factor has been shown to be of great importance by Pelet-Jolivet² and by Briggs and Bull³ who studied it quantitatively.

The adsorption theory has been shown by Briggs and Bull to apply strictly to the dyeing of wool with acid dyes. They showed that acid dyes are taken up by wool best from acid solution and that the amount taken up increases with the hydrogen ion concentration. They also showed that addition agents, as sodium sulphate, change the amount adsorbed, and in this instance that the sodium sulphate decreases the adsorption as demanded by the theory. The theory should apply to the dyeing of silk in the same way and this will be shown later in this paper.

Basic Dyes and the Adsorption Theory

With basic dyes the theory is stated as follows. "A basic dye is taken up most readily in an alkaline solution but may be taken up in a neutral or acid solution. This follows from the fact that in the case of basic dyes the color is in the basic radical of the dye, the dye dissociating in aqueous solution giving colored cations. Hence if the dye is present in an alkaline dye-bath the hydroxyl ions, being as a rule adsorbed more than any other univalent anion present, promote the adsorption of the full color base of cations. The presence of cations in the bath other than those of the dye will cause the amount of a basic dye taken up by the fibre to be cut down. In the same way readily adsorbed anions will increase the adsorption of the dye. Addition of sulphuric acid to the dye-bath will cause more of a basic dye to be adsorbed than

¹ J. Phys. Chem., **26**, 846 (1922).

² Chem. Abs., **2**, 2159 (1908).

³ J. Phys. Chem., **26**, 845 (1922).

an equivalent amount of hydrochloric acid or than the addition of isohydric hydrochloric acid. The addition of sodium sulphate will increase the amount of basic dye taken up by the fibre."

Briggs and Bull have studied the dyeing of wool with basic dyes and have shown it to be an adsorption phenomenon. The theory being correct should hold for silk in the same manner as for wool. This will be shown to be the case later in this paper.

Although basic dyes are not very fast to light and washing, they are used extensively with silk because they give colors of great brilliancy with this fibre. Moreover the requirements of fastness to light and washing are not so strict, as a rule, for silk. Hübner¹ says that the dyeing of silk is strictly a physical or mechanical operation. Pelet-Jolivet² shows that in dyeing silk with a basic dye, methylene blue, the amount of dye taken up is a maximum in alkaline solution, and a minimum in acid solution. Data obtained by them are given in Table I.

TABLE I

Adsorption of Methylene Blue by Silk

Volume of dye bath 50 cc.

Concentration of Methylene Blue = 0.8%.

Weight of silk = 0.3 g.

Fibre	2 cc. N/10 HCl	Methylene Blue adsorbed, mg	
		Neutral Solution	2 cc. N/10 KOH
Silk	1.3	10.8	40.6

This is as it should be for, according to the theory, basic dyes should be taken up best from alkaline solution. Both Briggs and Bull and Pelet-Jolivet give data showing how the adsorption of basic dyes by wool varies with increasing alkalinity in the first case and with increasing acidity in the second case. This checks the theory. Only the above data for silk are available. Results similar to those for wool should be obtained for silk. The variation in the adsorption of basic dyes by silk in acid solution will be shown later.

Pelet-Jolivet³ in studying the effect of addition agents in the dye-bath found that 0.5 grams of silk in 50 cc. of 0.2 percent methylene blue solution took up 18.4 mg. dye with sodium sulphate in the bath and 10.8 mg. when alone. These data point to the theory being correct when applied to the dyeing of silk.

However, H. Salvaterra⁴ made a quantitative study on the dyeing of silk with basic dyes, dyeing the silk with a series of closely related dyes. He found from his experiments that the amount of color taken up varied in the same manner as the molecular weights of the color bases. He concluded from these experiments that the dyeing was a chemical process and supported the theory

⁴ J. prakt. Chem. **88**, 502 (1913).

of salt formation between the color base and the silk. The data from which he drew these conclusions are given in Table II.

TABLE II
Dyeing of Silk with Basic Dyes

Time of run 1 $\frac{1}{2}$ hours.

Temperature boiling water bath

Dyestuff	Material for run Silk	Dye	Found on 1 g. silk	Mol. Wt. of dye	(A) Ratio of Mol. Wt.	(B) Ratio of dye on 1 g. silk	Diff. A and B
p-Fuchsin	4.79	1 21	0.022	305	1 00	1 00	0 0
Fuchsin	7 43	1.87	0 024	333	0 92	0 92	0 0
New							
Fuchsin	8.78	2 23	0 026	347	0 88	0 85	3 2
Crystal							
Violet	6.76	1 69	0 030	389	0 78	0 74	5 7
New Solid							
Green 3B	9.39	2.36	0 032	415	0 73	0 69	5 6

These results which are the only data given by Salvaterra are hardly sufficient ground on which to base his conclusions. His data given for the amount of dyestuff taken up by one gram of silk must have been calculated from the amount taken up by the different amounts of silk he used with the different dyes. These amounts of dye "taken up by one gram silk" therefore are not comparable and his values as listed are not necessarily what one gram of silk alone would have adsorbed. One thing he should have done to substantiate his theory was to have studied the variation in the concentration of the dye in the bath and the dye in the fibre in a series of experiments with a given dye.¹ "If the dye forms a sparingly soluble compound with the fibre, the fibre and the compound with the fibre would form two separate phases and consequently the composition of the dye in the bath would stay constant as long as any of the fibre compound was forming. Then the concentration of the bath would vary and that of the dye in the fibre would stay constant. In case it was adsorption the concentration of the dye in the bath and in the fibre would vary continuously." Salvaterra also forgot or neglected to consider the work of Sisley² who dyed silk with fuchsine and decolorized it. The operation was repeated several times without the silk losing weight. This³ is a "decisive proof against the assumption that a salt formation had occurred between the dye and the fibre." Another factor which seems to disprove the chemical theory is the work of Freundlich and Losev.⁴ They state that the "partition of a basic coloring matter between carbon or silk, etc., and an aqueous solution follow the same law and that it is adsorption." Silk would

⁴ Z. physik. Chem., **59**, 284 (1907).

have to play the part of an acid or a base in this case which might be but it seems impossible for one to have to consider, in the same way, carbon acting as an acid or base.¹

Because of the data of Pelet-Jolivet² pointing to the correctness of the adsorption theory and because no adsorption curves for the dyeing of silk had been made it was deemed necessary to substantiate the adsorption theory as applied to the dyeing of silk. It is found in commercial dyeing of silk that the addition of sodium sulphate to the bath cuts down the amount of dye taken up whether acid or basic. This is a further reason for checking the correctness of the adsorption theory.

The first part of this paper is concerned with showing that the adsorption theory is correct, applying to the dyeing of silk exactly as for wool.

Experimental

The silk used in this work was a first-class grade of degummed silk, obtained through the courtesy of Professor T. B. Johnson of Yale. In some earlier work done on the adsorption of tannic acid by silk, this commercial silk was heated in a ten percent soap bath for one hour at 95°C. This process was repeated using a five percent soap bath to ensure complete degumming. The silk was then washed thoroughly with distilled water to remove the soap and dried. Experiments showed, however, that this was not necessary. The silk as supplied had been degummed as completely as possible, because the silk as supplied and that undergoing the further treatment gave results which agreed closely enough to make it possible to dispense with the soap treatment.

The dyes used were supplied by E. I. duPont de Nemours and Company for the earlier work of Briggs and Bull in their study of the dyeing of wool. The acid dye employed was duPont Orange II and the basic dye duPont Crystal Violet E.

The "bast soap" used in the latter part of the work was made by degumming raw silk, using neutral, powdered sodium oleate, as supplied by Powers-Weightman and Company for the degumming agent. The raw silk was degummed by heating first in a ten percent soap bath for one hour at 95°C and then in a five percent soap bath for the same time and at the same temperature. After using the soap baths for several successive treatments the soap becomes thoroughly charged with the sericin and this liquor was used as the bast soap.

The general procedure throughout the work was to make up a dye-bath of known composition to a total volume of 250 cc. This was then attached to a return condenser to prevent evaporation and heated to the temperature of the boiling water bath, about 95°C. One-gram pieces of silk were placed in the bath at this temperature and kept at this temperature for forty-five minutes. At the end of this time the silk was removed directly from the hot bath. The bath was then allowed to cool down to room temperature.

¹ Bancroft, J. Phys. Chem., **18**, 2 (1914).

² Pelet-Jolivet: "Die Theorie des Färbeprozesses" 95, 118 (1910).

The amount of dye taken up by the fibre was determined by difference after the amount left behind in the bath had been determined. The amount left behind in the bath was determined by titration of aliquot portions of the cooled bath with titanium trichloride. The method followed is that suggested by Knecht¹ which had been successfully used later by Salvaterra,² Briggs and Bull,³ and Paddon.⁴ The titanous chloride used was standardized directly in terms of the dye being used by titrating a standard solution of the dye to a colorless solution. During the titration the solution titrated was boiled and air was excluded, being displaced by an atmosphere of hydrogen. Orange II titrates to a colorless endpoint in the presence of an excess of Rochelle salt. Crystal Violet E in the presence of Rochelle salt titrates to a colorless endpoint with the separation of a white precipitate which does not interfere, however, with seeing the endpoint. Sodium bicitrate, quite by accident, was found to work very well in this titration. In the presence of this compound Crystal Violet E titrates to a colorless endpoint without the separation of the white precipitate. The change from Rochelle salt to sodium bicitrate does not affect the result in any way and should not, for Piccard⁵ states that the tartaric acid in Rochelle salts exerts a catalytic action on the action and he recommends the use of one percent hydrofluoric acid which acts similarly. Sodium bicitrate presumably acts in exactly analogous manner.

Determination of the dye left in the bath containing "bast soap" at first presented one difficulty. Titration of an aliquot portion of a dye-bath containing this soap resulted in the use of more of the standard titanous salt than corresponded to that required for the dye when present alone. This difficulty was first met by standardizing the titanous chloride with a standard containing the same percentage of soap as used during a series of runs. This difficulty disappeared when sodium bicitrate was used in the place of the Rochelle salt. Using the bicitrate the volume of titanous chloride checked very closely when titrating a standard containing soap and when titrating a standard with no soap.

Final hydrogen ion concentrations were determined in the case of the experiments with Orange II to see if as in the case of wool the amount of dye taken up varied continuously with the hydrogen ion concentration. The hydrogen electrode was used in these determinations. The electrode vessel employed was the simplified form of the Lewis, Brighton, and Sebastian device.⁶

Hydrogen used for the electrode was electrolytic hydrogen from a tank and before using was passed through alkaline pyrogallol, water and sulphuric acid. Passing the hydrogen through a quartz tube containing a heated nichrome spiral was not resorted to as it has been found not to be necessary.

⁵ Piccard: Ber., 42, 4341 (1919); Knecht: "New Reduction Methods in Volumetric Analysis," 8 (1918).

⁶ J. Am. Chem. Soc., 39, 2250 (1917).

Saturated calomel electrodes were used as the standards and the potentials were measured at room temperature using a Leeds and Northrup precision potentiometer. It is not necessary in work of this type to use an instrument as sensitive as this one since the accuracy of determinations of pH of dye-baths is not exceedingly great.

Silk and Hydrochloric Acid

First a study of the adsorption of an acid by silk was made. Concentration of acid in the bath and of acid in the fibre should vary continuously if the silk shows adsorption of the acid. One gram pieces of silk were heated

FIG. 1
Adsorption of HCl by Silk

at the temperature of the boiling water bath with dye-baths of known composition and the acid adsorbed determined by difference after the acid left in the bath had been determined. The data for this series of experiments are given in Table III.

TABLE III
Adsorption of HCl by Silk

Weight of silk 1 g.

Volume of bath 250 cc.

Temperature Boiling water bath.

cc. N/10 HCl at start	cc. N/10 HCl at end	cc. N/10 HCl adsorbed
1.0	0.76	0.24
2.0	1.34	0.66
3.0	2.18	0.82
5.0	4.05	0.95
7.0	5.99	1.01
10.0	8.84	1.16
15.0	13.64	1.36
25.0	23.48	1.52

These data show that the acid concentration in the bath is varying continually, as it should for adsorption. Plotting these data a curve is obtained which shows this very plainly as seen in Fig. 1.

Acid Dyes and Silk

Silk was next dyed with Orange II in acid solution for, according to the theory, acid dyes should be taken up best from acid solution. The silk was entered at the temperature of the boiling water bath and removed at the same temperature. The results of the experiments are given in Table IV.

TABLE IV
Adsorption of Orange II by Silk

Volume of dye bath	250 cc.		
Weight of silk	1 g.		
Amount of dye	75 mg.		
Temperature	Boiling water bath		
Time of run	45 minutes		
	cc. N/10 HCl at start	mg. dye adsorbed	Final pH
	0.0	2.8	7.34
	1.0	16.4	4.17
	2.0	27.7	3.95
	3.0	37.9	3.07
	4.0	40.35	2.72
	8.0	43.08	2.37
	15.0	45.5	2.17
	25.0	30.0**	1.70
	50.0	47.7	1.53

**The value for the amount of dye adsorbed in this case is obviously wrong.

From these data it is clearly seen that the amount of dye taken up varies continuously with hydrogen ion concentration. As the hydrogen ion concentration increased, the amount of dye taken up also increased. This is in accord with the theory which formulated an increase in adsorption of acid dyes in acid solution.

Next a study was made of the effect of the addition of sodium sulphate when added to the dye bath. The conditions were kept exactly the same as before except for the addition of the tenth-normal sodium sulphate solution.

TABLE V

Effect of Sodium Sulphate on Adsorption of Orange II by Silk

Volume of bath	250 cc.		
Weight of silk	1 g.		
Amount of dye	75 mg.		
Temperature	Boiling water bath		
Time of run	45 minutes		
	cc. N/10 HCl added	cc. N/10 Na ₂ SO ₄	mg. dye adsorbed
	10.0	0.0	38.67
	10.0	25.0	27.78

These two experiments show that the addition of a strongly adsorbed anion as the sulphate anion cuts down the adsorption of the dye. This is as it should be. No further work was done with the effect of sodium sulphate on the dyeing with acid dyes except later to see the effect played by bast soap in silk dyeing. The reason for not carrying these experiments any farther here was that greater interest centered upon the basic dyes.

From these two sets of experiments one is safe in concluding that the dyeing of silk by acid dyes is an adsorption phenomenon.

Basic Dyes and Silk

Experiments were next made, dyeing silk with basic dyes. The basic dye employed was duPont Crystal Violet E which can easily be determined by titration with titanous chloride in the presence of an excess of either Rochelle salt or sodium bicitrate.

According to the theory of dyeing, basic dyes should be taken up most from an alkaline solution. An attempt was made to dye silk with Crystal Violet E in alkaline solution. When the silk was added to the hot bath the colorless leuco base was precipitated. However this dye can be used in neutral or slightly acid solution. Commercially it is used in slightly acid solution.

A study was made of the dyeing of silk with Crystal Violet E in acid solution. The first experiments were made with the bath acidified with sulphuric acid. The results are shown in Table V.

TABLE VI
Adsorption of Crystal Violet E by Silk

Volume of bath 250 cc.
Weight of silk 1g.
Amount of dye 75 mg.
Temperature Boiling water bath
Time of run 45 minutes

cc. N/10 H ₂ SO ₄ added	mg. dye adsorbed
0.0	48 3
2.0	21 5
5.0	9 0

These experiments show that more dye is taken up in neutral solution than in acid solution and that the amount taken up in acid solution decreases with increasing acidity. These results agree with the theory.

Since acetic acid is used to a great extent in the dyeing of silk with acid and basic dyes, a study was made with it replacing the sulphuric acid. The results of a set of experiments are shown in Table VII.

TABLE VII

Adsorption of Crystal Violet E by Silk from Baths acidified with Acetic Acid

Volume of bath	250 cc.
Weight of silk	1 g.
Amount of dye	75 mg.
Temperature	Boiling water bath
Time of run	45 minutes

cc. N/10 CH_3COOH	mg. dye adsorbed
0.0	48.3
2.0	25.5
5.0	16.3

Comparison of these results with those of Table VI shows that more dye is taken up in baths acidified with acetic acid than from baths acidified with an equivalent amount of sulphuric acid. This is as it should be. Two factors play a part in determining this difference. First the difference in the adsorption of the sulphate and acetate ions would lead one to conclude that the adsorption ought to be greater from sulphuric acid baths. This follows from applying the Schulze-Hardy valence rule which would predict a greater adsorption of the sulphate anion than the acetate anion because of the difference in their valences. However the more important factor in this case is the degree of ionization of the two acids. Acetic acid is considered a weak acid while sulphuric acid is relatively a strong acid. At 25°C . a solution of sulphuric acid containing 0.05 mols of acid per liter (tenth normal) is 64.8 percent ionized while a 0.1 molar acetic acid solution (tenth normal) is only 1.3 percent ionized. As a result the adsorption of hydrogen ions by the silk in case of the sulphuric acid baths would be greater and the amount of dye taken up would necessarily be cut down over that for the acetic acid baths. The results shown by Tables VI and VII are in agreement with the theory.

A study was then made of the effect of addition agents on the dyeing of silk with basic dyes, the one studied being sodium sulphate as before.

TABLE VIII

Effect of Addition Agents (Sodium Sulphate) on the Adsorption of Crystal Violet E by Silk

Volume of bath	250 cc.
Weight of silk	1 g.
Amount of dye	75 mg.
Temperature	Boiling water bath
Time of run	45 minutes
Bath acidified with sulphuric acid	

cc. N/10 H_2SO_4	cc. N/10 Na_2SO_4	mg. dye adsorbed
0.0	0.0	48.3
2.0	0.0	21.5
5.0	0.0	9.5
5.0	25.0	17.5

This was repeated using N/10 acetic acid in place of the sulphuric acid. The results of a series of experiments are shown in Table IX.

TABLE IX

Effect of Sodium Sulphate on the Adsorption of Crystal Violet E by Silk in CH_3COOH Baths

cc. N/10 CH_3COOH	cc. N/10 Na_2SO_4	mg. dye adsorbed
0.0	0 0	48.3
2.0	0.0	25.5
5.0	0.0	16.3
5.0	25.0	35.5

Another series of experiments was run to show that this effect is general and not specific for a given acid concentration. The data are given in Table X.

TABLE X

Effect of Sodium Sulphate on Adsorption of Crystal E by Silk from CH_3COOH Baths

cc. N/10 CH_3COOH	cc. N/10 NaSO_4	mg. dye adsorbed
0 0	0 0	54.7
1 0	0 0	29.1
1 0	25.0	36.6
2.0	0 0	22.1
2.0	25.0	26.67
3 0	0 0	17.8
3 0	25.0	20.6

These results agree very nicely with the theory. The addition of a strongly adsorbed anion as the sulphate ion should increase the adsorption of the dye and this is shown very clearly by the above data.

The results of the work done so far can be summarized by saying that the adsorption theory does apply very satisfactorily to the dyeing of silk when the silk is dyed with either acid or basic dyes. It now remains to be shown why in commercial practice sodium sulphate apparently decreases the amount of an acid or basic dye taken up by silk.

Practical Silk Dyeing

In the practical dyeing of silk there is added to the dye-bath a certain percentage by volume of "bast soap," or "boiled off liquor." Bast soap is the product obtained by the heating of raw silk with hot strong soap solutions. The raw silk fibre is composed essentially of two parts, the outer casing called sericin or silk glue and the inner fibre or fibroin. The reeled silk as it appears in trade consists of 70-75 percent of fibroin and 30-25 percent of sericin or silk glue. The sericin causes the raw fibre to be harsh and rough; containing most of the coloring matter it gives to the raw fibre the straw-colored appearance which is associated with it. The sericin is soluble in hot soap baths and

is easily removed by heating with soap. The soap is used for many treatments and becomes heavily charged with the waxy and glue-like sericin. This heavily sericin-charged soap is called bast soap or boiled-off liquor and is very much used in making up dye-baths for silk dyeing.

The *addition of bast soap* to the dye-bath is the factor which causes sodium sulphate apparently to *cause a decrease in the amount of a basic dye taken up*.

The use of bast soap in the art of silk dyeing has long been resorted to. Napier¹ says that Perkins in his original statement stated "that in silk dyeing the principal difficulty is due to the great affinity of the dyes for the fibre which prevents even dyeing. After a time it was found that this could be overcome by dyeing the silk in a weak soap lather. This causes dyeing to proceed less rapidly and keeps the face of the silk in good condition.

Matthews² states that silk is usually dyed with basic dyes in a dye bath containing "boiled-off liquor" broken or neutralized by acetic acid. He also states that ordinary soap can be used in the place of the bast soap or that it may be omitted entirely, the dye-bath being made up with acetic acid alone. Matthews³ gives the following reasons for the use of boiled-off liquor:

1. "The boiled-off liquor acts as a regulator in the dyeing process; retards the adsorption of color and gives more regular and better penetrated dyeings."

2. "Its use prevents loss of weight of the silk especially if there is much silk glue still left on the fibre."

3. "It adds to the softness and lustre of the dyed silk."

Whittaker⁴ says that basic dyes are best applied in a perfectly neutral bath or in a boiled-off bath just neutralized or broken with acid. He says that the acid in the bath keeps the color off the silk and prevents good exhaustion of the dye-bath.

Numerous other references could be given which deal with the dyeing of silk and the author in every case mentions or recommends the use of boiled-off liquor in silk dyeing.

Matthews⁵ states: "though the practice of using bast soap has been carried on for a long time and is almost universal, the absolute necessity of its employment has been questioned. Ganswindt⁶ claims to have shown by practical tests that the results obtained without the boiled-off liquor are equally as good as those obtained otherwise, the lustre, feel of fibre, and other properties being the same. Though the presence of the bast soap retards the velocity of dyeing (aiding the penetration and evenness of the color), it also prevents good exhaustion of the dye-bath which is a draw-back." Matthews, as stated above, says that the boiled-off liquor may be omitted. Springer⁶ says it is not necessary to use boiled-off liquor if the silk is completely degummed

¹ Napier: "Manual of Dyeing," 382 (1875).

³ Matthews: "Application of Dyestuffs," 197-199 (1920).

⁴ Whittaker: "Dyeing with Coal Tar Dyes," 16 (1919).

⁵ "Theorie und Praxis der modernen Färberei," II, 16.

⁶ "Dyestuffs," 24, 56 (1923).

It has been shown in this paper that the adsorption theory does apply to the dyeing of silk when dyed in the absence of boiled-off liquor. It remains now to show experimentally that bast soap does cut down the amount of dye taken up and to show why.

Experiments were carried out to show the decrease in adsorption of dyes by silk in the presence of bast soap. The bast soap used was prepared as described at the beginning of this paper. The results with acid dyes are given in Table X.

TABLE X
Adsorption of Orange II by Silk in the Presence of Bast Soap

Volume of bath	250 cc.			
Weight of silk	1 g.			
Amount of dye	75 mg.			
Temperature	Boiling water bath			
Time of run	45 minutes			
cc. N/10 HCl	cc. N/10 Na ₂ SO ₄	cc. bast soap	mg. dye adsorbed	
10 0	0 0	0 0	38.67	
10 0	25 0	0 0	27.78	
10 0	25 0	25 0	6.00	

These results check commercial practice. Since acid dyes are affected in this manner it would be natural to expect basic dyes to act in the opposite way, namely that bast soap should force the dye on the fibre. Experimental results showed, however, that, just as in the case of acid dyes, the amount of basic dyes adsorbed in the presence of bast soap was decreased materially. Data for Crystal Violet E and Silk are given by Tables XII and XIII.

TABLE XII
Adsorption of Basic Dyes by Silk in the Presence of Bast Soap

Volume of bath	250 cc.			
Weight of silk	1 g.			
Weight of dye	75 mg.			
Temperature	Boiling water bath			
Time	45 minutes			
cc. N/10 H ₂ SO ₄	cc. N/10 Na ₂ SO ₄	cc. bast soap	mg. dye adsorbed	
0.0	0.0	0.0	48.3	
2.0	0.0	0.0	21.5	
5.0	0.0	0.0	9.5	
5.0	25.0	0.0	17.5	
5.0	25.0	25.0	6.1	

This was repeated replacing the sulphuric acid by acetic acid. The data for these experiments are given in Table XIII.

TABLE XIII

Adsorption of Crystal Violet E by Silk in Presence of Bast Soap

cc. N/10 CH_3COOH	cc. N/10 Na_2SO_4	cc. bast soap	mg. dye adsorbed
0.0	0.0	0.0	13.3
2.0	0.0	0.0	25.5
5.0	0.0	0.0	16.3
5.0	25.0	0.0	35.5
5.0	25.0	25.0	4.5
45.0	25.0	25.0	2.9
70.0	25.0	25.0	20.0

It is thus shown clearly that the addition of bast soap to the dye-bath cuts down the adsorption of a basic dye by silk. The high result with acetic acid in Table XIII is explained by a decrease in solubility of the dye when a large volume of acetic acid was added to ensure complete neutralization of the bast soap. This result, however, is in accord with the theory for the amount of dye taken up is still less than when bast soap was omitted from the bath.

It was thought that the same result, decrease in adsorption, could be obtained by dyeing first in a bath containing only the soap and secondly repeating but adding sodium sulphate to the bath. A series of experiments were made varying the different substances in the bath. The data obtained are given by Table XIV.

TABLE XIV

Adsorption of Crystal Violet E by Silk reversing the Order of adding Assistants to the Dye bath

Volume of bath 250 cc.

Weight of silk 1 g.

Weight of dye 75 mg.

Temperature Boiling water bath

Time of run 45 minutes

cc. N/10 CH_3COOH	cc. N/10 Na_2SO_4	cc. bast soap	mg. dye adsorbed
0.0	0.0	0.0	52.7
0.0	0.0	25.0	4.1
0.0	25.0	25.0	2.9
5.0	0.0	25.0	4.0
5.0	25.0	25.0	2.6

The results of this series of experiments show that the bast soap in every case causes a decrease in the adsorption of the dye by the fibre.

This can only be explained by saying that in both cases the bast soap as a whole is taken up preferentially by the fibre and as a result the amount of dye adsorbed by the fibre is cut down materially. Another factor which undoubtedly aids in the case of Crystal Violet E is that Crystal Violet is

considered to be partly colloidal.¹ Diffusion experiments indicate this to be the case with Crystal Violet E. This means that the dye may act to some extent as a substantive dye, especially in the presence of a peptizing agent. Some of the bast soap might act as the peptizing agent and in this way cut down the adsorption to a certain extent. This has been shown to be the case with substantive dyes by Briggs.²

Summary

1. A study has been made of the adsorption theory of dyeing, applying it to the dyeing of silk with acid and basic dyes.
2. The dyeing of silk has been found to be an adsorption phenomenon and follows the adsorption theory conclusively.
3. The action of assistants has been studied, in particular the action of sodium sulphate and bast soap. The action of sodium sulphate checks the theory.
4. The results obtained in practice which apparently contradict the theory are due to the presence of bast soap or boiled-off liquor in the dye-bath.

Tannin Mordant

Tannins have been used for a long time as a mordant, both for cotton and for silk.

Bancroft³ mentions the fact that the "aborigines of North America used sumac as a mordant to fix the red coloring matter of a species of galium on porcupine quills. He also states, p. 117, "that cotton can be dyed with quercitron bark by impregnating the fibre with the astringent matter of myrobolans, rendering to a great extent the use of aluminum acetate unnecessary. In describing the dyeing of cotton with madder, p. 178, he mentions the fact that the cotton can be mordanted first with sumac followed by treatment with alumina. Slater⁴ states that the consumption of galls in printing and dyeing is very limited, being used in the production of the best class of blacks upon silk. He mentions the use of other tannins such as divi-divi, catechu, and sumac in printing and dyeing operations. Dreaper⁵ says that tannic acids are of the greatest value to the dyer of cotton, forming lakes with basic dyes. On silk he believes that they play the part more of a dye than a mordant. Hummel⁶ states that tannic acid acts as a mordant toward coloring matters of basic character such as magenta and malachite green.

Tannins are used on cotton for a mordant largely for basic dyes. The fibre is treated with tannin, for example a decoction of galls, and the adsorbed tannin is fixed by means of tartar emetic. This is necessary in the case of

vegetable fibres for Knecht and Kershaw¹ have shown that tannic acid adsorbed by vegetable fibres is easily washed out by cold water. Georgievics² studied the adsorption of tannin by cotton and concluded that:

(1) The tannin vat never becomes exhausted.

(2) Adsorption depends less upon the actual amount of tannin in solution than upon the concentration. In practice as concentrated a bath as possible is used. Gardner and Carter³ state that the adsorption of tannin by cotton is increased 48-50 percent by the addition of lower fatty acids such as acetic acid. HCl has little or no effect, while sulphuric acid has a detrimental effect. Knecht and Kershaw⁴ studied the adsorption of tannin by cotton under various conditions and they conclude that the best condition for adsorption is to enter the cotton at 100°C and allow to cool with occasional stirring for three hours. They also show that the most tannin is taken up from the more concentrated solutions which is what one should expect.

Tannin is used with silk largely to produce a good grade of black and for weighting by successive alternate treatments with tannin and ferric salt. Vignon⁵ studied the adsorption of tannic acid and gallic acid by silk. He concludes that ungummed silk can adsorb gallic and tannic acids and that the tannic acid is adsorbed more readily than gallic acid, the limit being 25 percent of the weight of the silk. Heermann⁶ also studied the taking up of tannin by silk and states that silk behaves like hide in that it adsorbs a large amount of tannin from cold solutions and as much as 25 percent from a hot solution. He further states that the tannin adsorbed is not readily removed by water. Sisley⁷ studied the effect of the addition of acids on the adsorption of tannin and finds that if silk is stirred in a dilute solution of tannin containing no acid only a small amount of tannin is adsorbed. If mineral acid is present the adsorption is practically complete. He also states that silk will adsorb tannin from more concentrated solution in the absence of acid. He gives no data to show what the effect of acid would be in the case of more concentrated solutions.

Ganswindt⁸ states that of the organic mordants tannin is used to a great extent for silk. He also says, p. 21, that the adsorption from warm baths, (up to 50°C), is purely a mechanical and not a chemical process and that the tannin taken up from such baths can be removed by washing with water and still easier by washing with soap. From hot baths silk can take up 20-25 percent of tannin which is fast to washing and retained firmly even if treated with soap solution.

This paper deals with the adsorption of tannin by silk.

Experimental

The silk used in this work was obtained through the courtesy of Professor T. B. Johnson of Yale. The tannins used were J. T. Baker's U. S. P. Tannic Acid, powdered prepared from Chinese nutgalls and Zinsser's U. S. P. Tannic Acid, powdered and Tannic Acid XXX.

One-gram pieces of silk were placed in tannin baths of known composition either at room temperature or at the temperature of the boiling water-bath while attached to a return condenser to prevent evaporation and kept at the required temperature for forty-five minutes. The silk was entered and removed at the temperature maintained throughout the experiment.

The tannin adsorbed was determined by difference after determining the amount of tannin left in the bath at the end of each experiment. The tannin left in the bath was determined by the use of the Loewenthal method.¹ The solutions were standardized against a tannin solution of known concentration.

The effect of temperature on the amount of tannin adsorbed by silk was studied first. The results of a series of experiments are given in Table XV.

TABLE XV

The Effect of Temperature on Adsorption of Tannin by Silk

Volume of bath 100 cc.
Weight of silk 1 g.
Time of experiment 45 minutes

g. tannin taken	g tannin adsorbed	
	Room temp.	Temp. of boiling water bath
0.250	0.0277	0.087
0.50	0.0301	0.120
2.0	0.0436	0.170

These results show clearly that more tannin is taken up by silk at higher temperatures. Knecht² says that the greatest amount of tannin is taken up at the point of incipient boiling.

The effect of varying the concentration was next studied and that data obtained are given in Table XVI.

TABLE XVI

Effect of Concentration on Adsorption of Tannin by Silk

Volume of bath 100 cc.
Weight of silk 1 g.
Temperature Boiling water bath
Time of Experiment 45 minutes

g. tannin taken	adsorbed	g. tannin taken	adsorbed
0.125	0.025	0.50	0.100
0.250	0.0551	1.00	0.150
0.375	0.090	2.00	0.170

¹ J. prakt. Chem., **81**, 150 (1860); Z. anal. Chem., **16**, 201 (1877); **20**, 91 (1881).

² Knecht, Rawson and Loewenthal: "A Manual of Dyeing," **1**, 190.

These results show that there is a continual variation in the amount adsorbed, indicating that there is no compound being formed and that the taking up of tannin by silk is an adsorption phenomenon. At least this is true over the range given.

Experiments were next carried out to see if the amount of tannin taken up by the silk from cold tannin baths was a function of time. At the temperature of the boiling water bath forty-five minutes were sufficient to bring about maximum adsorption. At room temperature the amount taken up during the same period was relatively small. It was thought that if at room temperature the silk was left till equilibrium was reached the amount of tannin adsorbed by the silk would undoubtedly be equal to the amount taken up at the higher temperature or might exceed it. Considerable difficulty was met in trying to carry out the experiments over a relatively long period of time. Mould formed in the solutions, usually within a week, making the experiments failures. This difficulty was finally overcome by sterilizing both the solution and the silk, allowing them to cool to room temperature and entering the silk at that temperature. The data obtained are given in Table XVII.

TABLE XVII
Effect of Time on the Adsorption of Tannin by Silk
from Cold Tannin Baths

Volume of bath	100 cc.		
Weight of silk	1 g.		
g. tannin taken	duration of experiment	temperature	g. tannin adsorbed
0.25	45 minutes	room	0.0277
0.25	31 days	room	spoiled
0.50	45 minutes	room	0.0301
0.50	31 days	room	0.0502
0.50	120 days	room	0.1306
0.50	45 minutes	boiling water bath	0.1200

These results show clearly that the adsorption of tannin by silk from cold baths is a function of time.

The effect of acids on the adsorption of tannin by silk was next studied. Sulphuric acid was used with the dilute solutions so as to prove or disprove the work of Sisley. With more concentrated solutions both sulphuric and acetic acids were tried. The data are given in Table XVIII.

These results show that in dilute solution acid does help in adsorption of tannin but that its effect is not so marked in more concentrated solution.

Finally the effect of washing on the fastness of the tannin adsorbed was studied. Silk that had been treated either in the cold or in the hot was washed with water and a portion of the washed silk treated with a solution of ferric chloride and the depth of the black produced noticed. The remaining

TABLE XVIII
Effect of Acid on Adsorption of Tannin by Silk

Volume of bath	100 cc.			
Weight of silk	1 g.			
Temperature	Boiling water bath			
Time	45 minutes			
g. tannin taken	cc. N/10 H_2SO_4	cc. N/10 CH_3COOH		g. tannin adsorbed
0.02	—	—		0.002
0.02	40.00	—		0.012
0.50	—	—		0.100
0.50	25.00	—		0.110
0.50	50.00	—		0.120
0.50	—	50.00		0.120

silk was washed again and the treatment of a portion of the silk so washed repeated with ferric salt and the black produced compared with the first or preceding samples. This process was repeated several times, washing first with water and finally with soap. The silk that had been treated in the cold with the tannin gave up its tannin easily to the water as the inked samples of silk showed. Those silks which had been treated in the hot retained the tannin firmly, even on being washed with soap solution.

Summary

1. A preliminary study has been made of the adsorption of tannin by silk.
2. More tannin is taken up from hot solutions than from cold solutions. If equilibrium is reached in the cold the amount taken up approximates that taken up in the hot.
3. Addition of acids aids to a slight extent in the adsorption of tannin by silk in the hot.
4. Tannin taken up in the cold is fairly easily removed, while tannin taken up in the hot is retained much more firmly.
5. No explanation can be given at present for the effect of temperature on the adsorption of tannin.

Tannin and Electrolytes

Tannins are astringent substances, many of which are glucosides. They exist in the colloidal state in solution.

Tannins are amorphous, slightly acid, and vary in color from dark brown to pure white. They are as a rule peptized by water, alcohol, acetone, ethyl acetate, and glycerol. They are not peptized by chloroform, benzene, petroleum ether, carbon disulphide, and fixed and volatile oils.

Some tannins give blue-black precipitates with ferric salts and others give green-black precipitates. This is generally given as one method of classifying the different tannins.

A large number of inorganic salts precipitate or coagulate tannin solutions. Most tannins give brown precipitations with potassium dichromate.¹ Lime water gives precipitates which vary in color.² Saturated solutions of calcium chloride, sodium chloride, and potassium acetate precipitate them.³ Lead and copper acetates⁴ as well as ammoniacal zinc acetate⁵ have all been used to precipitate tannins in suggested methods of analysis. Stannous chloride,⁶ nickel hydroxide,⁷ and tartar emetic⁸ have also been used to precipitate tannin. Ammonium molybdate precipitates most tannins.⁹ Aluminum oxide¹⁰ has been suggested as a substitute for hide powder in the official method of analysis as adopted by American and English chemists. Other salts which precipitate tannin solutions are ammonium chloride, cobalt acetate, manganese acetate and uranium acetate.

Mineral acids such as hydrochloric and sulphuric acid precipitate tannins but this will be discussed at length later for this paper has to deal with the precipitation of tannins by these two acids.

The tannins in addition to being precipitated by inorganic salts are active reducing agents. They reduce gold and copper solutions and absorb oxygen from the air, especially in alkaline solution. The fact that they are good reducing agents has been made use of in the Loewenthal method of tannin analysis using potassium permanganate.

The glucoside tannins are hydrolyzed by dilute acids yielding glucose as one of the products.

The action of the tannins with mineral acids has been studied since the tannins were first isolated as a new class of substance, about 1790¹¹. Dize¹² first called attention to the precipitate caused by the addition of HCl to an infusion of galls. Davy¹³ mentions the precipitate obtained by acids with tannins. Trommsdorf¹⁴ studied the precipitates formed by the addition of HCl and H₂SO₄ to astringent substances. Berzelius¹⁵ proposed a method of analysis based on the formation of a precipitate with a clear infusion of nut galls by H₂SO₄. Etti in 1887 precipitated oak bark tannin by HCl. Most authors of textbooks in their discussion of tannin state that tannins are pre-

precipitated by dilute mineral acids. Among these authors are to be found Remsen,¹ Norris,² and Behal.³

Thomas and Foster,⁴ with the hopes of throwing some light upon the colloidal nature of tannin, again studied the action of various electrolytes upon numerous tannin extracts. A study of their results brings out the following points:

Oak bark tan liquors are precipitated more and more with increasing acid concentration of hydrochloric acid and sulphuric acid. Acetic acid gives no appreciable precipitation in any case but with higher concentrations the suspended matter begins to dissolve. Formic acid gives similar results. Lactic acid behaves similarly to formic acid but dissolves the suspended matter at lower concentration.

Barium chloride and calcium chloride both give increasing amounts of precipitate with increasing concentration. Aluminum sulphate causes a rapid increase in precipitate, passing through a maximum and then a slower increase.

Wilson⁵ considers these results as a salting out. Thomas and Foster,⁶ in the interpretation of their results, say that the effect of the electrolyte is masked by the salting out and chemical precipitation of molecularly dispersed substances in addition to the colloidal tannins present.

It seemed worth while to determine whether all the tannin of one kind comes out at a given concentration of the precipitating agent as is the case with sols stabilized entirely by an adsorbed ion.

The work of Thomas and Foster was repeated following the method outlined by them. The tannins used were:

(1) U.S.P. Tannic Acid, Powdered, J. T. Baker Chemical Co. This tannin is made from selected Chinese nut-galls.

(2) U.S.P. Tannic Acid, Powdered, Zinsser and Co.

(3) Tannic Acid X.X.X., Zinsser and Co. This last tannin is one of exceptional purity.

Solutions of each tannin were made up so that 100 cubic centimeters of solution contained 4 grams of solid matter. The solutions were made at 85°C, cooled to 35°C and adjusted to final volume. It was found unnecessary with these tannins to centrifuge the stock solution to throw down coarse suspended matter. 25 cc. portions of the stock solution were placed in 50 cc. graduated centrifuge tubes and an equal volume of electrolyte added. The tubes were then centrifuged for five minutes at 1000 times gravity. The volumes of the precipitate were then recorded.

Using hydrochloric acid as the electrolyte the results obtained are given in Table XIX.

⁶ J. Ind. Eng. Chem., 14, 194 (1922).

It is seen clearly from Table XIX that no precipitate was obtained with either tannin till a concentration of 2 molar acid was reached in the case of Zinsser's tannic acid. In both cases when precipitation started the volume of precipitate increased with increasing acid concentration. In all cases the precipitates formed with very strong acid varied from those obtained with acids of weaker concentration, by being less dense. This was very noticeable with concentrated acid. These results are shown graphically by Fig. 2, as are also the data obtained by Thomas and Foster. They obtained precipitates with most tannins with acids which were relatively very weak compared with

FIG. 2
Precipitation of Tannins

TABLE XIX
Precipitation of Tannins by Hydrochloric Acid

Tannin used 25 cc. of 4 percent solution

Electrolyte used 25 cc.

Conc. of electrolyte added	Volume of precipitate in cc.	Conc. of electrolyte added	Volume of precipitate in cc.
	Baker's U.S.P.		Zinsser's X.X.X.
M/100-2 M	0.00	M/100-2 M	0.0
2.0 M	0.00	2 M	0.25
3.0 M	0.00	3 M	0.50
4.3 M	0.50	4 M	—
5.0 M	—	5 M	1.75
6.6 M	3.00	6 M	3.00
7.0 M	4.5	7 M	—
8.0 M	5.0	8 M	4.5
9.0 M	8.0	9 M	5.0
Conc. HCl	9.5	Conc. HCl	7.0

the acid of lowest acid concentration precipitating the tannins used during these experiments. With acids of low concentration they were undoubtedly also precipitating foreign matter, other than tannin.

With sulphuric acid as the electrolyte experiments were carried out only with J. T. Baker's Tannic Acid. The results of the experiments are given in Table XX.

TABLE XX

Precipitation J. T. Baker's U.S.P. Tannic Acid, Powdered by Sulphuric Acid

Tannin taken 25 cc. of 4 percent solution

Volume of electrolyte 25 cc.

Conc. of acid added	Volume of precipitate	Conc. of acid added	Volume of precipitate
M/100-2M	0.0 cc.	6 M	10.0
3M	0.5	7M	14.0
4M	3.0	8M	16.0
5M	7.0		

The volume of precipitate formed increased with increasing acid concentration. The difference in the character of the precipitate with stronger acid solutions was very marked here.

Acetic acid did not give a precipitate with any of the three tannins. The acid concentration in this case was varied from 0.005 molar to glacial acetic acid.

Barium chloride did not give a precipitate with Baker's Tannic Acid, U.S.P. powdered or Zinsser's Tannic Acid, U.S.P. powdered. With Zinsser's Tannic Acid X.X.X. a precipitate was obtained with all concentrations of solutions used. The volume of the precipitate was small, 0.25 cc. throughout except with a saturated solution of barium chloride when the volume increased to 0.50 cc.

The character of the precipitate, as noted above, varied with increasing acid concentration. The question immediately arose whether the volume of precipitates obtained with different acid concentrations were comparable with reference to the amount of tannin actually precipitated.

Twenty-five cc. portions of a four percent tannin solution were precipitated with 6M HCl and concentrated HCl respectively and the volumes noted. The precipitates were analyzed for tannin using the Loewenthal method of analysis. The results are given by the following data:

Precipitant	Volume of precipitate	g. tannin found	Ratio of volumes	Ratio of g. tannin
6M HCl	3.0 cc.	0.385	2.1	1.46
conc. HCl	6.5	0.570		

The volume ratio indicates that more than twice as much tannin was precipitated with concentrated HCl as with 6M HCl. The actual amount of tannin precipitated, determined by analysis, was approximately only one and a half times as much with concentrated HCl as with 6M HCl.

It follows from these experiments that the tannin is not precipitated completely at a given concentration of acid and that the volumes of precipitates, obtained with solutions of increasing acid concentration, are not comparable. The volumes of precipitate do not represent the relative amounts of tannin actually precipitated.

These conclusions were confirmed further by other experiments. Tannin was precipitated with acid of a given concentration and then 25 cc. of the filtrate was treated with an equal volume of the same precipitant. In every case more tannin was precipitated. Data obtained are given in Table XXI.

TABLE XXI

Additional Precipitation of Tannin from Original Filtrate by Original Precipitant

Tannin J. T. Baker's U.S.P.

Precipitant	Volume of precipitate Original solution	Filtrate
6M HCl	2.0 cc.	0.50 cc.
7M HCl	3.7	0.25
8M HCl	4.5	0.25
conc. HCl	6.0	0.10

Results of the same type and order were obtained using Zinsser's Tannic Acid U.S.P. and Tannic Acid XXX as shown in Table XXII.

TABLE XXII

Additional Precipitation of Tannin from Original Filtrate by Original Precipitant

Tannin Precipitant	Zinsser's U. S. P. Vol. of precipitate		Zinsser's X X X Vol. of precipitate	
	Original	Filtrate	Original	Filtrate
5M HCl	—	—	1.75 cc.	0.25
7M HCl	3.5 cc.	0.10 cc.	3.0	0.10

The results given in Tables XXI and XXII show that the tannin is precipitated incompletely in the original precipitation.

Incomplete precipitation of the tannin and unreliability in the volume of the precipitates were again shown in another series of experiments. Tannin was precipitated by acid of a given concentration. The precipitate was peptized in water and reprecipitated by acid of the same strength. When the precipitate was completely peptized the volume of precipitate on reprecipitation indicated complete precipitation. Analysis of the precipitates for tannin showed incomplete precipitation. Data obtained in this experiment are given in Table XXIII.

TABLE XXIII

Tannin	Precipitant	Original Volume	Volume after peptization and re- precipitation	Tannin by analysis	
				1st ppt	2nd ppt
Baker U.S.P.	6M HCl	2.5 cc.	2.5 cc.		
	7M HCl	4.5	4.5	0.539	0.376
Zinsser U.S.P.	7M HCl	4.0	5.0	0.595	0.397

It is evident that the tannin is not precipitated completely and that the volumes obtained do not represent the effect of the electrolyte on the actual amount of tannin precipitated. Hence curves of the type drawn by Thomas and Foster do not represent the effect of the various electrolytes on the actual amount of tannin precipitated. Therefore, the curves are not of much value.

Another source of error which may interfere is hydrolysis. This factor is of greater importance when using mineral acid as the electrolyte. Fischer and Freudenberg¹ state that hydrolysis of a tannin with five percent sulphuric acid at 100°C is nearly complete after 60-70 hours. Hydrolysis would decrease the amount of tannin precipitated.

Summary

Tannins are coagulated by mineral acids and the volume apparently increases with increasing acid concentration. The volumes of tannin coagulated in the experiments described above do not necessarily represent the true effect of the electrolyte because of experimental error due to lack of analysis. The curves of the type drawn by Thomas and Foster are therefore not of any appreciable value. Sources of error in the method of Thomas and Foster are:

(1) The amount of tannin precipitated being determined by volume gives chance for error since the character of the precipitate varies considerably with different factors, such as acid concentration.

(2) The volume of precipitate does not represent the relative amount of tannin precipitated. The volume may be doubled but the actual amount of tannin precipitant may only be slightly increased.

(3) Precipitation is not complete. In some cases the volume relations indicated complete precipitation.

(4) Hydrolysis of the tannin, particularly when mineral acid is used, may result, reducing the volume of the precipitate.

The precipitation of the tannin in the above cases by mineral acids is due to at least two factors:

(1) Adsorption of hydrogen ion.

(2) A decrease in the peptizing action of the water. The peptization of tannin is apparently chiefly a peptization by water and only very slightly an electrical stabilization.

Acknowledgments

To Professor W. D. Bancroft, under whose direction this work was carried on, I desire to express my gratitude for his suggestions and unfailing interest.

It is also a pleasure to acknowledge my debt to my aunt, Miss M. E. Sherman, whose unfailing interest and help has made it possible for me to complete this work.

I also acknowledge gratefully the courtesies of Professor T. B. Johnson of Yale and of Zinsser and Company, who supplied the silk and several tannin samples respectively.

April, 1926.*

A FURTHER STUDY OF THE ABSORPTION SPECTRA OF POTASSIUM FERRO- AND FERRICYANIDES

BY FREDERICK H. GETMAN

In a former paper on the absorption spectra of the ferro- and ferri-cyanides of potassium¹ it was pointed out that the absorption spectra of the so-called α and β ferrocyanides described by Briggs² are identical, thereby furnishing additional evidence in support of the claim made by Bennett³ that these salts are not isomeric.

It was also pointed out that a slight but nevertheless well-defined difference exists between the absorption spectra of the α and β ferricyanides of potassium described by Locke and Edwards.⁴

It may be recalled that these investigators were the first to show that when a solution of ordinary red, or α - $K_3Fe(CN)_4$, is treated with a dilute acid and then precipitated with alcohol, an olive-green salt, corresponding to the formula, $K_3Fe(CN)_6 \cdot H_2O$, is formed. This salt they designated as β potassium ferricyanide. This salt was shown by its discoverers to differ in many of its reactions from the ordinary, or α potassium ferricyanide. For example, on treating a solution of the β -salt with a dilute solution of bismuth nitrate no precipitate is formed, whereas when the ordinary or α -salt is similarly treated with bismuth nitrate a copious yellow precipitate is thrown down. Notwithstanding the attempts of Bellucci and Sabatini⁵ on the one hand, and of Hauser and Biesalski⁶ on the other, to disprove the statements of Locke and Edwards relative to the existence of these two modifications of potassium ferricyanide, the work of the latter investigators was completely confirmed by Wells who repeated their experiments with great care and convinced himself of the correctness of their conclusions.

While the results of our earlier spectroscopic study of these substances are thus seen to be in perfect agreement with the contention that Briggs' so-called α and β ferrocyanides do not exist, whereas the α and β ferricyanides of Locke and Edwards are well-defined chemical compounds, it has seemed desirable to repeat our work with more refined apparatus. In our earlier studies the absorption spectra were photographed by means of a small Hilger quartz spectrograph, size E₃ I, and the resulting plates were measured and the absorption curves mapped by the familiar method of Hartley and Baly. In the present work a large Hilger quartz spectrograph, size E₃, with wave-length scale, was used in conjunction with a Judd Lewis sector photo-

meter to determine the curves of absorption. The tilt of the camera of the spectrograph was adjusted by preliminary trials with a copper spark until the readings of the wave-length scale agreed with the values of the wave-lengths of the principal lines of the copper spectrum as given in a table of standard wave-lengths. In all of the subsequent experiments a condensed

FIG. 1

spark between nickel-steel electrodes was used as the source of ultra-violet radiation. In order to make sure that no narrow absorption bands had escaped notice, owing to discontinuities in the iron-nickel spectrum, a source of continuous ultra-violet radiation was employed with the spectrograph alone.

An apparatus similar in principle to that devised by Fulweiler and Barnes¹ was constructed in which an electric discharge between tungsten wires under water constituted the source of continuous ultra-violet radiation extending to $\lambda_2 = 210 \mu\mu$. In the production of the spark discharge, the primary terminals of a $\frac{1}{4}$ kilowatt transformer specially designed for spectrum work were connected with the 110 volt A. C. lighting circuit. The secondary terminals were connected with two $\frac{1}{4}$ kilowatt condensers in parallel, each condenser having a capacity of approximately 0.03 microfarad. An adjustable spark gap, against which a current of air was directed by means of a small rotary blower, was joined in series with the tungsten electrodes. The tungsten wires forming the electrodes were 2 mm. in diameter and were so arranged

that the length of the spark gap could be easily adjusted by means of regulating screws. The most satisfactory length of spark under the electrical conditions which prevailed was found to be approximately 0.5 mm. With the slit of the spectrograph adjusted to 0.05 mm., a two minute exposure was found ample to give a thoroughly satisfactory spectrogram.

The special mounting shown in Fig. 1 was developed in the course of this investigation and because of its convenience in bringing the source of radiation into final adjustment we digress for a brief description of its salient features. By means of clamps attached to the vertical rod, R, the specially designed Pyrex flask, A, carrying the spark gap, G, was fastened at approximately the correct height before the slit of the spectrograph.

¹ Fulweiler and Barnes: J. Franklin Inst., 194, 83 (1922).

The final adjustment was effected by means of the screw, B, which operates against the spiral spring, C. A similar adjustment in a horizontal plane can be made by means of the screw, D.

FIG. 2

The methods employed in the preparation of the salts and the procedure followed in making up the solutions were similar to those described in our earlier paper.

The measurements of the plates obtained with the spectrograph and sector photometer are represented graphically in Fig. 2, where molecular extinction coefficients are plotted as ordinates against the corresponding wave-lengths (or their reciprocals, known as wave-numbers) as abscissae. Employing ab-

sorption tubes 20 mm. in length, it was found that the optimum concentration for complete mapping of the absorption curves of both the ferro- and ferricyanides was 0.0005 molar.

It will be observed that the absorption curves of the so-called α and β ferrocyanides of potassium are coincident. While thus confirming the conclusions drawn from our previous examination of the absorption spectra of these two substances, a comparison of the actual curves of absorption established by the two series of experiments reveals a marked disagreement between them. The experimental method employed in the earlier work, how-

FIG. 3

- | | | |
|-----|--------------------------------|------------------------------------|
| (A) | Spectrum of source. | |
| (B) | Absorption spectrum of 0.0005N | $\alpha\text{-K}_3\text{Fe(CN)}_6$ |
| (C) | " " | $\beta\text{-K}_3\text{Fe(CN)}_6$ |

| (E) | " " | $\beta\text{-K}_4\text{Fe(CN)}_6$ |

ever, being little better than qualitative, we believe that the curve shown in Fig. 2 may be accepted as representing the variation of absorption with changing wave-length of incident radiation within the limits of experimental error.

In our earlier study of the absorption of ultra-violet radiation by the α and β ferricyanides of potassium we were led to believe that a well-defined although slight difference exists in the absorptive properties of these two salts. The data which we have now obtained with the spectrophotometer leaves no doubt as to the validity of our former statement. As in the case of the ferrocyanides, however, the actual form of the absorption curves is found to be quite different from that previously plotted from measurements of the plates by the so-called Baly method.

Owing to the relatively sparse distribution of lines in those regions of the iron-nickel spectrum where it was especially desired to confirm the existence of absorption bands in solutions of both ferro- and ferricyanides, the tungsten spark under water was employed. As has already been stated, this source of ultra-violet radiation gives a continuous spectrum to $\lambda = 210\mu$. By means of this source it was possible to secure spectrograms which confirmed in a most satisfactory manner the existence and position of the absorption bands. In Fig. 3 is shown a spectrogram obtained with 0.0005 molar solutions of α and β ferrocyanides and α and β ferricyanides in tubes 40 mm. long. The

spectrum immediately below the scale is that of the source alone, while the succeeding spectra correspond to α ferricyanide, β ferricyanide, α ferrocyanide and β ferrocyanide respectively. That a marked difference exists between the absorption spectra of the ferro- and ferricyanides is clearly shown by the spectra in Fig. 3.

Summary

The results of further spectroscopic examination of the ferro- and ferricyanides of potassium contained in the foregoing pages may be briefly summarized as follows:

(1) The molecular extinction coefficients of the compounds designated by Briggs as α and β ferrocyanides of potassium have been determined and found to be identical. This result supports the view advanced by Bennett that these salts are not isomeric as claimed by Briggs.

(2) In like manner the molecular extinction coefficients of the α and β ferricyanides of potassium have been determined and found to be appreciably different from each other, thereby confirming the statement of Locke and Edwards as to the probable isomerism of these two compounds.

(3) An apparatus for producing sparks under water between tungsten electrodes has been employed in a further examination of solutions of the ferro- and ferricyanides with a view to detecting any narrow or weak absorption bands which might otherwise have been overlooked within the spectral range involved.

(4) The absorption spectra of the ferro- and ferricyanides of potassium have been shown to differ markedly from each other.

THE CATALYTIC ACTIVITY OF METALLIZED SILICA GELS

IV. The Oxidation of Methane

BY L. H. REYERSON AND L. E. SWEARINGEN

A great many investigations have been carried out having as their basis the oxidation of methane. The researches of Bone and Wheeler and their co-workers are well known. In recent years Berl and Fischer¹ have studied the oxidation of methane at temperatures above 400°. They find small amounts of formaldehyde under certain conditions. Tropsch and Rollen² also studied this reaction passing the mixed gases through heated quartz tubes at rather rapid rates. The best results obtained by these investigators corresponded to a conversion of about six per cent of the total methane to formaldehyde. Because of the interest which attaches to the oxidation of methane it was thought that a study of the activity of metallized silica gels on this reaction might lead to interesting results in the field of partial oxidation of hydrocarbons.

Experimental

The same experimental procedure was used in this work and the same catalysts used as in the previous paper by the authors on the synthesis of water. A gas absorption pipette containing a solution of KOH was added to the gas analysis system to take care of the CO₂ formed by oxidation. The gases were streamed at rates varying from 15 cc. to 200 cc. per minute through an apparent volume of 5cc. of catalyst. The reaction was studied with the catalyst maintained at temperatures varying from 200° to 400°. The gases after reaction were analysed for carbon dioxide and oxygen. Preliminary experiments showed that the only oxidation product of methane present in analizable quantity was carbon dioxide.

Results

The results of the experiments are given in Tables I to IV and in Fig. 1. The symbols used have the following meaning:

- A—The percent of methane in the original mixture.
- O₂—The percent of oxygen in the original mixture.
- A'—The percent of methane in the exit gas.
- O₂'—The percent of oxygen in the exit gas.
- f—The fraction of the exit gas found to be CO₂.
- F—The percent of the exit gas found to be CO₂.
- x—The fraction of the original methane oxidized.
- X—The percent of the original methane oxidized.
- A"—The calculated percent of methane in the exit gas.
- (O₂)"—The calculated percent of oxygen in the exit gas.

¹ Z. angew. Chem., **36**, 297 (1923).

² Brennstoff Chem., **5**, 37 (1924).

In the following reaction, $\text{CH}_4 + \frac{1}{2}\text{O}_2 \rightarrow \text{CO}_2 + 2\text{H}_2\text{O}$ if the fraction of methane oxidized is x , then the percent of methane in the gas mixture after the reaction is given by

$$A'' = \frac{100 (A - Ax)}{(A + \text{O}_2 - 2Ax)} \quad (1)$$

Likewise the percent of O_2 in the final mixture is

$$\text{O}_2'' = \frac{100 (\text{O}_2 - 2Ax)}{(A + \text{O}_2 - 2Ax)} \quad (2)$$

FIG. 1
Rate-conversion Curves for the Oxidation of Methane

The percent of CO_2 in the gases after reaction is given by

$$F = \frac{Ax}{(100 - 2Ax)} \quad (3)$$

where $F = 100f$.

It is evident that the amount of methane oxidized is equal to the amount of carbon dioxide formed. For the value of x we have

$$x = \frac{100f}{A + 2Af} \quad (5)$$

Substituting the value of x from (4) in (1) and (2) we have

$$A'' = A + f(2A - 100)$$

and

$$\text{O}_2'' = \text{O}_2 + 2f(\text{O}_2 - 100)$$

The values of A'' and O_2'' given in the tables are calculated from the experimental value because f is determined experimentally. The value of O_2' was determined experimentally and the value of A' was determined by difference. The values in the tables are expressed in percentage.

Discussion of Results

The results for the copper and silver catalyst are very interesting. It is evident in the case of both of these catalysts that in the early stages of the reaction oxygen is being removed from the gas stream and that this oxygen is not used in the oxidation of methane. This is indicated in Tables I and II when successive samplings are made at the same streaming rate. After the first removal of oxygen the silver catalyst shows practically zero activity throughout the temperature range studied while the copper continues to show catalytic activity. Because of this removal of oxygen in the early

FIG. 2
Time Efficiency Curves--Oxidation of Methane

stages of reaction additional experiments were carried out. With the aid of a by pass tube around the catalyst samples were collected and analysed at $2\frac{1}{2}$ minute intervals. The results of these experiments are shown graphically in Fig. 2. In the case of the copper catalyst the temperature was 360° while in the case of the silver the curves for both 360° and 200° are given. Curves A in the case of both catalysts give the amounts of oxygen found in the gases after reaction at 360° . Curves B are for the oxygen calculated to be present from the amount of CO_2 formed and curves C are for the amounts of CO_2 found in the exit gases. Curve A' for silver is for the amount of oxygen found at 200° and Curve D gives the calculated oxygen content at 200° from the CO_2 found. There was no CO_2 found at 200° so D gives the value for the O_2 in the original gas mixture.

These experiments show quite definitely that the oxygen, which first reaches the copper and silver deposited on the silica gel, is taken up by these metals almost completely. It may be strongly adsorbed or else combined chemically to form the oxide. Since it is impossible to differentiate between these two states at present it is easier to conclude that chemical combination has taken place. In the case of copper it is probably another case where the copper must be partially oxidized before it will act as a catalyst in oxidations.

This accounts for the strange shape of the curve for the copper catalyst at 400° as shown in Fig. 1. The first measurements were made on a fresh catalyst and the first three points are those taken successively at about the same rate of flow. After reaching an equilibrium state of oxidation the catalyst behaved just as the platinum and palladium catalysts. In order to account for the rather large amount of CO_2 produced initially at 360° in the case of the silver catalyst one has to assume that the silver was acting as an oxidizing catalyst prior to being oxidized itself or else there was some adsorbed CO_2 in the catalyst. This does not seem reasonable because there was none found at 200° where adsorption should be better than at 360° . The instability of silver oxide at higher temperatures accounts for the fact that more oxygen was removed at 200° .

In the case of the platinized gel no such removal of oxygen was observed in the initial stages of reaction. The reaction seems to quickly reach an equilibrium state. Furthermore, the rate of streaming does not have much effect on the efficiency of the reaction as long as the methane is in excess. The reaction becomes measurable at about 240° . Small increases in oxygen content produce increases in the amount of oxidation. This does not hold over the total range of concentrations because an excess of oxygen does not produce complete oxidation. In fact the catalyst is less sufficient when the oxygen content is high than when it is low. For example a change from twenty to twenty-eight percent in the oxygen content of the gas sample increased the amount of methane oxidized from about twelve percent to more than nineteen percent. On the other hand an oxygen content of seventy-three percent only gives an oxidation of eight percent and the efficiency of the catalyst falls off rapidly as the rate of gas flow increases. As in other catalytic studies there is apparently a definite concentration ratio of oxygen to methane which will produce the best results. These experiments also indicate that the methane must reach the catalyst surface before it is oxidized.

In the case of the palladium catalyst the reaction does not become measurable until 330° or nearly 100° above that at which the platinized gel causes oxidation. The same general results were obtained for the palladium catalyst as for the platinum except that the palladium was less efficient at a given temperature Table IV shows that increases in the oxygen content at low concentrations of oxygen causes more reaction while oxygen in excess leads to lessened reaction. The difference in the efficiency between the platinum and palladium may be due to the fact that the platinized gel is a slightly better adsorbent of oxygen. This is shown in the adsorption studies¹ on these gels.

Summary

1. With the exception of the silver catalyst the metallized silica gels have been shown to act catalytically in the oxidation of methane. They promote the complete oxidation of methane, yielding carbon dioxide and water. No partial oxidation products were found.

¹ Reyerson and Swearingen: J. Phys. Chem., 31, 88 (1927).

2. The copper catalyst is apparently oxidized to a considerable extent and then the copper oxide or the copper, copper oxide acts as the catalyst. The copper catalyst starts the reaction at a temperature as low as 200° .
3. The efficiency of the platinum and palladium catalysts depends upon the oxygen content of the gas mixture.
4. The platinized gel initiates reaction at a temperature as low as 240° while the palladium does not become active until about 330° . The platinized gel was found to be the most active of the catalysts in this reaction.

FACTORS AFFECTING THE COAGULATION OF COLLOIDAL CLAY

BY RICHARD BRADFELD*

Extensive field experiments are now in progress in many countries for testing the effect of different coagulating agents upon the physical properties and productivity of agricultural soils. It has long been known that the application of the divalent calcium ion in sufficient quantity will bring about an improvement in soil structure which is in general regarded as due to a decrease in the degree of dispersion of the colloidal clay. The coagulation of clay by electrolytes has been much studied in the laboratory, but due partly to the great differences in the soils themselves, to differences in the methods used, and to the presence of uncontrolled variables our knowledge regarding the fundamental nature of the process is still extremely meagre.

An attempt has been made at the Missouri Laboratory to isolate some of these variables and to determine their effect under controlled conditions. It has been shown, in the case of acid clays, that very slight changes in the pH value obtained after mixing the electrolyte and the clay cause a very great change in coagulation value especially near the neutral point (1). With neutral or alkaline soils this effect is of course less pronounced (2). It has also been shown that in certain cases at least the nature of the anion has a specific influence that can not be attributed to changes in the hydrogen ion concentration. The coagulation value has been found to depend in a peculiar way upon the concentration of the clay sol. With a neutral salt like CaCl_2 or KCl the coagulation value is almost independent of the concentration of the clay, while in the case of the hydroxides of these metals the value increases in direct proportion to the concentration of the clay. Mixtures of the neutral salt and the hydroxide give values which, in general, tend to agree with one or the other or both constituents, depending upon the pH value produced.

The experiments just cited were carried out with a colloidal clay sol separated from the Putnam silt loam subsoil by means of the Sharples Laboratory Supercentrifuge by a method previously described (1). This natural sol contains from twenty-five to thirty milliequivalents of exchangeable bases per 100 grams of clay, of which about fifty percent are Ca, fifteen percent Mg and the rest largely Na and K. The sol contains from twenty-two to twenty-five milliequivalents of exchangeable H per 100 grams. The average saturation capacity of the colloid is from fifty-two to fifty-five milliequivalents per 100 grams. When we consider that the Ca ion is about ten times as efficient as a coagulating agent as the K ion, and that the former is readily displaced by the latter when the latter is introduced in the form of a neutral salt, it would seem quite natural to expect that the coagulation values obtained would be greatly affected by this exchange reaction. This has been found to be the case for other clays by Wiegner and Gallay (4).

*Department of Soils, University of Missouri, Columbia, Missouri.

Information regarding the role played by exchange reactions during the coagulation process can be obtained by conducting two parallel series of experiments in one of which the exchange reactions are allowed to proceed normally while in the other these reactions are either prevented or controlled.

It has been shown recently that a soil can be easily freed from exchangeable bases and saturated with hydrogen ions by electrodialysis (3). The reaction involved is apparently a simple hydrolysis of the surface ions of the alumino-silicate complex. If the calcium-saturated complex is represented as CaX then the reaction involved in electrodialysis is expressed by the equation:

The resulting electrodialyzed clay (H_2X) is well suited for coagulation studies because (1) it is free from ordinary electrolytes, (2) it is free from exchangeable bases, and (3) it may be easily saturated to any desired extent with any base by the addition of the proper amount of the proper hydroxide.

Experimental Method

Preparation of materials. The colloidal clay was separated from the subsoil of the Putnam silt loam by the method previously described. This soil was made up of particles under 100μ in diameter. The electrodialysis was carried out in an ordinary three-compartment cell between parchment membranes, using a platinum gauze anode and a nickel gauze cathode. A potential of 150 volts was applied to the electrodes and the dialysate was siphoned off periodically and replaced by distilled water. The dialysis was continued until the catholyte was free from bases. This required in most cases four to six days. The electrodialyzed clay was suspended in distilled water, the concentration determined by the pycnometer method and a series of dilute solutions prepared from this stock solution. The six percent stock solution had a pH value of 3.2 to 3.4 and a total acidity equivalent to fifty-five milliequivalents per 100 grams dry clay.

Determination of coagulation values. The coagulation values were determined by the same method used in the earlier experiments (1) using the concentric tube device suggested by Weiser except that in this case a smaller apparatus was used. Five cc. of the clay sol was measured into the outer space by means of a pipet, the desired amount of electrolyte was then measured into the center tube, and sufficient water added to bring the volume up to five cc. The clay and the electrolyte were then thoroughly mixed by inverting the cell quickly. After a thoro shaking, the mixture of clay and electrolyte was poured into test tubes and allowed to stand for fifteen minutes. The test tubes were then centrifuged for an additional fifteen minutes. The minimum concentration of electrolyte required to produce complete coagulation could in most cases be determined easily and fairly accurately by this method. The coagulation value is expressed in every case in terms of milliequivalents of Ca or K per liter. In most cases no difficulty was encountered in reproducing results. In every case the values plotted in the curves represent the average of at least four closely agreeing determinations.

Experimental Results

The effect of electro dialysis upon the coagulation values obtained with $\text{Ca}(\text{OH})_2$ are shown in Fig. 1. With this divalent base the coagulation value is a linear function of the concentration of the clay. (Curves A and B). The saturation curves C and D represent the amount of $\text{Ca}(\text{OH})_2$ required to neutralize the acidity of the colloidal clay as determined by potentiometric titration. In the case of $\text{Ca}(\text{OH})_2$ the increase in coagulation values resulting from

FIG. 1

Effect of concentration of the clay sol upon the coagulation values of clay before (B) and after (A) electro dialysis. Coagulating agent $\text{Ca}(\text{OH})_2$.

electro dialysis can be largely accounted for by the difference in the degree of saturation of the clay. In the case of both the natural and the electro-dialyzed sol the coagulation values are about double the saturation values. When KOH is used as the coagulating agent (Fig. 2), the effect of electro dialysis is much greater than it was with $\text{Ca}(\text{OH})_2$. This was of course expected as the bases removed by electro dialysis were largely Ca and Mg . The coagulation values increase with the concentration of the clay, but not linearly as in the case of $\text{Ca}(\text{OH})_2$. No explanation has been found for the upward inflexion on curve A. The influence of electro dialysis is most marked at the lower concentrations. In the case of the .25 percent sol (Concentration of clay is always expressed as concentration resulting after mixing with electrolyte) the coagulation value was increased from twenty-two to one hundred three as a result of electro dialysis. This shows quite conclusively the very important role that exchange reactions may play in coagulation phenomena. The difference between the coagulation values and saturation values are much greater in the case of KOH than with $\text{Ca}(\text{OH})_2$. The electrokinetic potential

of a potassium clay is much greater than that of a calcium clay and consequently a much greater excess of that cation is necessary to lower the potential to the critical value.

With the neutral salts of both KCl and CaCl_2 the coagulation values are practically independent of the concentration of the clay. (See KCl curve Fig. 3.) With mixtures of the bases and their neutral salts very complex

FIG. 2

Coagulation values of natural and electrolyzed colloidal clay with KOH as influenced by the concentration of the clay.

curves may be obtained. With a mixture of eight parts KCl and two parts KOH for instance, the coagulation values obtained with the .25 percent and the .50 percent sols are almost the same as those obtained with KOH alone, while with all clay sols above 1.5 percent the values obtained with this mixture are almost identical with those obtained with KCl alone. Quite frequently two different coagulation values could be found for the same electrolyte mixture, one of which was of the same order of magnitude as that of the neutral salt alone while the other approached that of the alkali alone. This anomalous behavior was in every case related to the pH value of the mixture. If a sufficient concentration of the cation were present to bring about coagulation at pH values less than six, then values similar to the neutral salt were obtained. If, however, sufficient base were present to render the mixture alkaline then values similar to those obtained with the pure base were obtained.

The effect of hydrogen ion concentration was even more pronounced in the case of the electrolyzed clay (Fig. 4) than it was in the case of the natural sol (Fig. 3). In Fig. 4 are shown the coagulation values as a function of the

final pH value. The values for the most dilute (.25%) and the most concentrated (3%) sols both before and after electro dialysis are shown. In the case of the electro dialyzed clay all the points are segregated into two very distinct zones. The first is an acid zone with pH values under five and coagulation values under five milliequivalents per liter. The second is an alkaline zone with pH values between eleven and thirteen and coagulation values between one hundred six and one hundred eighty. No distinct coagulation values were obtained between these two zones.

FIG. 3

Effect of concentration of clay sol upon coagulation values obtained with KCl, KOH and mixtures of these solutions.

With the natural clay there is also a tendency toward a low acid and a high alkaline coagulation zone. The zones are, however, much wider in pH range. With the .25 percent natural clay the coagulation values were constant between the pH values nine and twelve.

Discussion of Results

These experiments show quite conclusively that the coagulation value of a colloidal clay may vary widely with slight changes in either: (1) hydrogen-ion concentration, (2) concentration of the clay sol, or (3) in the nature and extent of the exchange reactions which take place when the coagulating agent is mixed with the clay. The effect of hydrogen-ion concentration is most marked when exchange reactions are prevented by the use of sols freed from exchangeable bases by electro dialysis. The two distinct critical pH value zones found with this purified clay are probably due to the fact that in the acid region the hydrogen clay which has a very small electrokinetic potential is being flocculated while in the alkaline region the potassium or calcium clay with much higher charges on the particle is involved. Two distinct consecutive reactions probably take place in the case of coagulation in an alkaline

medium. (1) The acidity of the clay itself must first be neutralized. The amount of base required for this purpose is, of course, directly proportional to the concentration of the clay. (2) A sufficient excess of electrolyte must then be added to coagulate the resulting Ca- or K-saturated clay. In the case of $\text{Ca}(\text{OH})_2$ the amount of base required for the neutralization of the acidity of

FIG. 4

Effect of pH value on the coagulation values—clay sols before and after electro dialysis. Coagulating agents, KCl, KOH and mixtures of these solutions.

the clay constitutes about 60% of the total required for coagulation. With KOH, however, the neutralization is responsible for 10 percent or less, (depending on concentration of the clay) of the total electrolyte requirement. This may be attributed either to specific differences in the absorbability of the two cations or possibly to differences in the amount of ionization at the surface of the particle. At any rate the cataphoretic potential of the potassium clay is much higher than that of the calcium clay, and a higher concentration of electrolyte is necessary to bring it to the critical point.

The effect of the concentration of the clay sol upon coagulation values proved to be quite complex. Only the monovalent K and divalent Ca ions were studied. With the neutral salts of these bases the values were practically independent of the concentration of the sol. With $\text{Ca}(\text{OH})_2$ the critical concentration was a direct linear function of the concentration of sol. With the KOH the values increased but not nearly as rapidly as with $\text{Ca}(\text{OH})_2$. When various mixtures of the bases and their neutral salts were used as coagulants very complex curves were obtained. The clever explanation offered by Kruyt (5) for the effects observed by earlier investigators of this problem will have to be amplified if they are to clarify satisfactorily all the observations made in this study.

The effect of exchange reactions upon coagulation values has been but little studied in the past. The very striking differences observed in the behavior of the natural clay and the electrodyalyzed clay sols show quite clearly, however, that these reactions may be of great importance.

A STUDY OF THE POTENTIALS AND ACTIVITIES OF THE METALS IN ZINC AMALGAM CELLS

BY J. N. PEARCE AND J. F. EVERSOLE

Electromotive force measurements of zinc amalgam cells have been made by Richards and Forbes,¹ Richards, Wilson and Garrod-Thomas² and by Hulett and Crenshaw.³ In these investigations different methods were used in preparing and handling the amalgams, but both were designed to give re-

FIG. 1

sults of a high degree of accuracy. There is, however, an unfortunate lack of agreement between the results obtained in the two laboratories. This is best shown by Fig. 1. All attempts to bring them into harmony, or to point out errors in either method of procedure, have failed.

Richards and his co-workers have measured the electromotive forces existing between various dilute amalgams in contact with a saturated solution

¹ Richards and Forbes: Pub. Carnegie Inst., 56; Z. physik. Chem., 58, 683 (1907).

² Richards, Wilson and Garrod-Thomas: Pub. Carnegie Inst., 118, Z. physik. Chem., 72, 129, 165 (1909).

³ Hulett and Crenshaw: J. Phys. Chem., 14, 175 (1910).

of zinc sulphate. They have also calculated the potentials which the amalgams would have, if they formed perfect solutions. For this calculation they used the familiar relation,

$$E = \frac{RT}{nf} \ln \frac{c_1}{c_2}, \quad (1)$$

in which c_1 and c_2 denote the respective concentrations of the zinc in the amalgams. They have found that the observed potentials are less than those calculated by (1), and, further, that the deviations from the calculated values increase as the concentration of the zinc in the amalgam is continuously increased.

In a similar study at 25° Hulett and Crenshaw have measured the electromotive forces of zinc amalgam cells over a concentration range, extending from the saturated two-phase amalgam to very dilute amalgams. In each case the potential was measured against the constant, easily reproducible two-phase amalgam. They found that for the range, 0.0061 N – 0.00000307 N, the potential between any two amalgams conforms to the laws of a perfect solution, as indicated by (1). The fact that these amalgams do appear to behave as perfect solutions for a given range of concentration and that they then suddenly become imperfect is difficult to comprehend.

Hildebrand¹ has measured the vapor pressure of mercury over zinc amalgams at 325° . From the results obtained he seems to have shown conclusively that zinc dissolved in mercury is polymerized according to the equilibrium relation, $2 \text{Zn} \rightleftharpoons \text{Zn}_2$. Applying the law of mass action, using mol fractions instead of concentrations, this equilibrium is given accurately by the equation,

$$K \left(\frac{1 + 2\alpha}{N + 1 - \alpha} \right)^2 = \frac{\alpha}{N + 1 - \alpha} \quad (1)$$

where N is the number of mols of mercury to one mol of zinc, α is the number of Zn_2 mols and K is the equilibrium constant. In this work he has assumed that the type of equilibrium existing is independent of the temperature, but that the value of the equilibrium constant changes with the temperature.

In a later work,² Hildebrand has shown that the electromotive force of a concentration cell containing liquid zinc amalgams is accurately given by the relation,

$$nE_f = RT \int_{N_1}^{N_2} N d \ln p., \quad (2)$$

By means of a series of mathematical deductions and substitutions, involving the Raoult vapor pressure law and equations (1a) and (2), he arrives finally at the equation,

$$E = 0.00019834 \frac{T}{n} \log \frac{1 + N_2 + \sqrt{N_2 + 2AN_2 + A}}{1 + N_1 + \sqrt{N_1 + 2AN_1 + A}} \quad (3)$$

¹ Hildebrand: Trans. Am. Electrochem. Soc., **32**, 335 (1912).

² Hildebrand: J. Am. Chem. Soc., **35**, 501 (1913).

In this n is the valence and N is the number of mols of mercury to one mol of zinc. $A = 4K + 1$, where K is the equilibrium constant of (1a). Hildebrand tested the validity of equation (3), using the electromotive force data collected by Richards and Forbes at 23.01°. For this he let $A = 11.6$, which implies a value of $K = 2.65$. The values of E thus calculated, and the observed values were found to agree within the limit of experimental error. He also calculated from his vapor pressure data the potentials which the same cells should have, if the zinc were not associated. In such cases, according

to the vapor pressure law, $p = p_0 \frac{N}{N+1}$, we find

$$N d \ln p = \frac{dN}{N+1},$$

which, on integration and substitution of the ordinary values of the constants, gives the relation,

$$E = 0.00019834 \frac{T}{n} \log \frac{N_2 + 1}{N_1 + 1}. \quad (4)$$

This equation follows directly from (3) in case the zinc were not associated, that is, when $K = 0$, and, therefore, when $A = 1$. When Hildebrand applied equations (3) and (4) to the data of Hulett and Crenshaw he found that, while the deviations from the ideal potentials are not far from those corresponding to the work of Richards and Forbes and to equations (3), the difference is, nevertheless, far greater than the maximum error claimed by the investigators. Moreover, he found that no value can be assigned to A which will bring the measurements of Hulett and Crenshaw into harmony with the theory.

In view of the discrepancies arising in the works of the investigators cited, we thought it worth while to repeat the study of the electromotive forces of zinc amalgam electrodes. To this end we have followed, in general, the procedure of Hulett and Crenshaw.

Materials and Apparatus

Mercury.—The mercury used in this work was purified by repeated spraying through dilute nitric acid, then dried by heating and fractionally distilled five times in a current of air under reduced pressure. It was finally dried by heating in an electric oven at 105° and stored in a vacuum desiccator.

Zinc Sulphate.—The zinc sulphate was purified by digesting Baker's "Analyzed" salt with zinc oxide and hydrogen peroxide to oxidize any ferrous iron. The solution was then filtered, made slightly alkaline with ammonia and hydrogen sulphide was added until a fairly heavy precipitate of zinc sulphide was formed. This mixture was digested for two days on a steam bath, then cooled and filtered. This procedure should remove any heavy metals which might have been present. The zinc sulphate was then allowed to crystallize, and it was subsequently recrystallized three times, the last time from conductivity water. The salt thus purified was used in preparing the electrolyte for the cells and also in preparing the zinc for the amalgams.

Zinc.—The zinc was prepared by the electrolysis of solutions of the purified zinc sulphate, using a cathode consisting of a 0.5 mm. tip of a small platinum wire sealed into the end of a glass tube. The current density was kept low so that a rather compact deposit of zinc was formed. The solution was kept neutral during electrolysis by surrounding the large platinum anode with a porous cup, filled with basic zinc sulphate prepared from the purified salt. The zinc obtained by electrolysis was washed, dried and twice fused

FIG. 2

with pure solid ammonium chloride to remove the occluded mother liquor. It was then distilled four times under reduced pressure in a Pyrex glass tube, the last distillation being made in an atmosphere of hydrogen. Under these conditions, no fog, due to oxidation, appeared as was the case when air was used instead of hydrogen. The bright crystalline zinc was then cut to convenient size by means of a clean steel "side cutters."

Hydrogen.—The hydrogen was prepared by the electrolysis of a strong solution of sodium hydroxide between nickel gauze electrodes. It was bubbled through an alkaline solution of pyrogallol to remove oxygen and then through a tower containing fused calcium chloride and soda lime.

The electrode vessels, eight in number, were made of Pyrex glass and were of the form shown in Fig. 2. In preparing a cell for use the cell was filled to about three quarters of its capacity with a solution of zinc sulphate, saturated at 25°, and the solution was then boiled for a short time under reduced pressure. The tube was then repeatedly filled with hydrogen and repeatedly evacuated. Finally, to remove the last traces of oxygen, the solution was

subjected to a long period of continuous stirring, accompanied by an intermittent glowing of the platinum wire, *c*. To prepare the amalgam the mercury was weighed in a special pipette, Fig. 2, B, and was introduced into one of the cups of the cell under hydrogen pressure. This was done by removing an electrode tube by breaking the cement seal at *d*, lowering the capillary of the pipette into the cell and breaking off the capillary tip at *h* by pressure against the bottom of the cell. The zinc was weighed accurately and then dropped into the mercury. During these operations a rapid stream of hydrogen was passed into the cell at *a* and out through the opening through which the addition was made. Amalgams made up in this manner have been kept for eight months without any evidence of surface oxidation.

The weights of mercury used are accurate to 0.10 mg., those of zinc to 0.01 mg. Each cell when made up contained one amalgam with exactly 2.22 g. of zinc in 100 g. of mercury. This gives a two-phase amalgam at 25°, and it is the amalgam against which the potential of each of the other electrodes was read.

All potential measurements were made by means of a high resistance, 5-dial Wolff potentiometer in series with a sensitive Leeds and Northrup galvanometer. By means of galvanometer deflections it was possible to read the potentials to ± 0.001 mv. The cells were immersed in a large oil thermostat which was electrically controlled to $\pm 0.01^\circ$ at any desired temperature. The temperatures were read by means of a standard thermometer, (B.S. No. 21577). The Eppley standard reference cell, (1.01891 v. at 25°), was kept constantly immersed in a separate oil-bath, maintained at $25^\circ \pm 0.01$.

The potential of each single phase amalgam was read against the two-phase reference amalgam at 18°, 25°, and 30°. This reference amalgam is two-phase at or below 25°, but becomes a single phase system at 30°. The potential between this standard reference electrode at 30° and an amalgam which is still two-phase at that temperature was determined

It was found that the concentrated amalgams at a given temperature give a constant potential indefinitely. The dilute amalgams show a tendency to increase in potential on standing. If, however, the amalgam is thoroughly mixed, it is possible to obtain potential readings at the three temperatures and then to return to the original temperature without any appreciable change in the electromotive force.

While the potentials of the amalgam cells were read at the three temperatures, the values differ so little that, for the sake of brevity, only those for 25° will be given. The values of $-E$ given in Table I represent the mean of many readings taken over a period of from two to ten days. In no case did the readings vary appreciably from the mean value. In this table N_2 is the mol fraction of the zinc in the amalgam, $-E$ is the potential of each individual amalgam against the most dilute amalgam, the values being calculated from the respective values of the potentials measured against the standard two-phase amalgam.

TABLE I

The activity of the zinc in the amalgams and the potentials, as well as the increase in free energy accompanying the cell process, are related by the well known thermodynamical expression,

$$\Delta F = E \cdot n \cdot f = RT \ln \frac{a_2}{a_2} \quad (5)$$

In this the values taken for the constants are: $f = 96494$ coulombs; $R = 8.316$ joules, and $n = 2$.

By rearranging (5), substituting the proper numerical values, and subtracting $\log N_2$ from both sides of the equation, we obtain

$$\log \frac{a_2}{N_2} = \left(\frac{-E}{0.0000922} \cdot \frac{1}{T} - \log N_2 \right) + \log a'_2. \quad (6)$$

At infinite dilution, or when a_2/N_2 becomes equal to unity, the left hand member of (6) becomes zero, hence

$$-\log a'_2 = \left[\frac{-E}{0.0000922} \cdot \frac{1}{T} - \log N_2 \right]. \quad (7)$$

If now we plot the values of the quantity in the brackets, as ordinates, against the mol fractions of zinc, as abscissae, the value of the ordinate where the curve cuts the vertical axis is equal to $-\log a'_2$. We have plotted these values

for the three temperatures and the curves are given in Fig. 3. The value for $-\log a'_2$ for 25° , at infinite dilution, is given in brackets at the top of the third column of Table I. By subtracting this value from the values of the ordinates at other values of N_2 , we have obtained the corresponding values of $\log a_2/N_2$. From these we have calculated the values of a_2/N_2 and a_2 found in the last two columns of this table. From the nature of the method used, it is

FIG. 3

obvious that the three curves of Fig. 3 must cross at a point corresponding to the most dilute amalgam. The nearer this point is to the vertical axis the less will be the inaccuracy introduced by extrapolation to the axis.

In passing, it is interesting to compare the activities which we have obtained for zinc with those which Lewis and Randall¹ have calculated for thallium from the data of Richards and Daniels.² They have found that the values of a_2/N_2 increases continuously with increasing concentration of thallium in the amalgam. With zinc amalgams, however, exactly the reverse is

¹ Lewis and Randall: "Thermodynamics," 267 (1923).

² Richards and Daniels: J. Am. Chem. Soc., 41, 1732 (1919).

true. The values of a_2/N_2 decrease as the concentration of the zinc is increased. This is precisely what we should expect, if the dissolved zinc is associated in the amalgam.

The variation of the activity of the two components of a binary mixture with change in concentration at a given temperature is given by the relation,

$$\log \frac{a_1}{N_1} = - \int_0^{N_2} \frac{N_2}{N_1} d \log \frac{a_2}{N_2}. \quad (8)$$

To determine the value of the $\log a_1/N_1$ for mercury at any concentration of zinc it is only necessary to plot the values of N_2/N_1 as ordinates against the corresponding values of $\log a_2/N_2$. The area under the curve from the origin, where $N_2 = 0$, up to the desired concentration N_2 gives directly the value of $\log a_1/N_1$ for the desired concentration. We have carefully plotted our values of N_2/N_1 against the corresponding values of $\log a_2/N_2$, and we have repeatedly measured the areas by means of a polar planimeter. The values for a_1/N_1 and a_1 for mercury thus calculated are given in the last two columns of Table II.

In order to determine the effect of temperature upon the electromotive forces of these amalgam cells, we made three sets of cells, one for each temperature, and each set containing exactly the same series of concentrations. These amalgams were prepared in a special pipette which enabled us to weigh

both the zinc and the mercury without mixing. After the pipette had been washed by a stream of pure dry hydrogen and evacuated, the mercury and zinc were mixed and thoroughly shaken. The cells were then sealed and placed in their respective temperature baths. The potentials were read over a period of several days, or until the potentials became constant. From the values of the electromotive forces thus obtained we have calculated the increase in free energy, $-\Delta F$, accompanying the dilution from the more concentrated amalgams, respectively, to the one most dilute. These values for the three temperatures are given in Table III.

Mean				+35.65			

The temperature coefficients of the electromotive force, and likewise of the change in free energy, were calculated from the potentials at the three temperatures by means of the equation,

$$E_t = E_{25} [1 + \alpha(t - 25) + \beta(t - 25)^2]. \quad (9)$$

These values are also included in Table III.

When the values of β are negligible, as they are for these cells, we may calculate the change in heat content, ΔH , accompanying the dilution from the known value of the free energy of dilution by means of the relation,

$$-\Delta H_{298} = -\Delta F_{298}(1 - \alpha_{.298}). \quad (10)$$

Furthermore, the change in entropy accompanying the dilution is given by the well known relation,

$$-\Delta S = \frac{\Delta F - \Delta H}{T}. \quad (11)$$

The values of ΔH_{298} and ΔS_{298} have been calculated and are to be found in the last two columns of Table III.

For purposes of discussion and comparison, Table IV has been arranged. In this Table E_o represents the observed potentials, E_i the ideal potentials

as calculated by (4), and E_c are the potentials calculated by (3). In these calculations $N_1 = 3305.9$, and N_2 is the mol ratio in the amalgam taken in conjunction with it. In the recalculation of the data of Richards and Forbes, Hildebrand has assumed the value $A = 11.6$. We have found, however, that the value, $A = 11.2$, when substituted in (3), gives better agreement with the observed values not only for the data of Richards and Forbes, but also for our own as well.

FIG. 4

While the differences between the observed potentials, E_o , and the ideal, E_i , do decrease with increasing dilution of the variable amalgam, N_2 , this difference does persist even at the lowest concentrations. To calculate this deviation for the most dilute amalgam, where $N_1 = 3305.9$, we have calculated the values of E_c and E_i by means of (3) and (4), respectively, and taking N_2 so large that A becomes negligible in comparison. For this purpose we have arbitrarily assumed N_2 to be 1000000, and that the resulting amalgam is so dilute that its potential is that of an ideal amalgam. Hildebrand used a similar method in calculating the electromotive force of the most dilute amalgam employed by Richards and Forbes. We have found the deviation for the amalgam, $N = 3305.9$, to be 0.020 mv. This value added to the original deviations gives the corrected deviations which are collected in column, ($E_o -$

E_1), of Table IV. The results show a very close agreement between observed and calculated potential values in the dilute range of concentration, but these values do diverge as we pass to higher concentrations of zinc. The deviations are best shown in Fig. 4. The curves show at once the close agreement between our data and those obtained by Richards and Forbes throughout the concentration range which they studied. They show also that Hildebrand's equation (3) applies with considerable accuracy through a large part of the concentration range which we have studied.

Reference should again be made to Fig. 1. In this are shown for comparison the plots of the deviations of the electromotive forces from the data of Richards and Forbes and from that of Hulett and Crenshaw. As stated before, the latter have found that the amalgams behave as ideal solutions up to the concentration at which $\log N = 2.51$. At this point the observed potentials begin to deviate from those calculated for ideal amalgams. Although we have repeated their work, using essentially their method throughout, we have been unable to duplicate their results. On the contrary, our results do confirm those of Richards and Forbes. We have shown that, throughout the whole range of concentration up to saturation, the deviations between the observed and ideal potentials increase regularly as we pass to higher concentrations of zinc. These deviations, on the other hand, approach zero at infinite dilution.

Summary

1. The electromotive forces of zinc amalgam concentration cells have been measured at 18°, 25° and 30°. The amalgam concentrations range from $N = 0.0003024$ up to saturation.
2. The change in free energy, heat content and entropy accompanying dilution have been computed.
3. The activities of the zinc and mercury in the various amalgams have been calculated.
4. The deviation between the observed and ideal potentials increases continuously with increase in the concentration of the zinc. It approaches zero at infinite dilution.
5. The results obtained confirm the work of Richards and Forbes.

THE BEHAVIOR OF METHANOL OVER ALUMINUM AND ZINC OXIDES*

BY HOMER ADKINS AND PHILIP D. PERKINS

A number of recent publications upon the formation of diethyl ether over oxide catalysts makes it seem advisable to submit some results obtained in 1924 upon the behavior of methanol over aluminum and zinc oxides. The experimental method was essentially the same as that previously described in the study of the dehydration and dehydrogenation of the higher alcohols.¹ That is, about 50 cc. of methanol per hour was passed over a gram of the catalyst heated in a Pyrex tube to 300 to 400°C. The reaction products were passed thru a condenser, then bubbled thru 10 cc. of concentrated sulfuric in each of two 8" \times 1- $\frac{1}{3}$ " test tubes and the undissolved gas collected and measured. The dimethyl ether in the condensate was boiled out at the end of an hour's run, collected in the sulfuric acid and then liberated, collected and measured over water. The ether was liberated by diluting the acid with water to about four times its volume and heating to boiling for a few minutes. The recovery of ether² is at least 99%. The catalysts were of the same sample as those previously used³ and had been used for an hour or two before each of the runs reported, so that their activity had become rather constant. Two thermocouples were used, the head of one being in the catalysts mass, and that of the other outside of the tube but in an indentation adjacent to the catalyst. The dehydration of methanol is a strongly exothermic reaction, so that the difference in temperature indicated by the thermocouples was in some cases as much as 45°.

The variation in the reaction with temperature is shown in Fig. 1. Curve 3 represents the total activity in liters of gas per hour and curve 4 the activity in liters of dimethyl ether per hour. The temperature shown is that of the inside thermocouple. Curves 1 and 2 show the same values for activities plotted against the temperature as indicated by the outside thermocouple. It is apparent from the curves that methanol is converted almost quantitatively over the alumina catalyst used into dimethyl ether in increasing amounts at temperatures up to about 350° and that there is little change in either activity or proportions of products over a range of perhaps 40°. Further increase of temperature results in a rapid increase in the products other than dimethyl ether (CO₂, CO, C₂H₄, H₂, and CH₄) partly at the expense of that compound.

The behavior of methanol over a zinc oxide catalyst is shown in Fig. 2, the temperature being that of a thermocouple in the catalyst mass. The forma-

FIG. 1
Methanol over Alumina

The liters of gas at 22° and 740 mm formed per hour by the passage of 50 cc of methanol over 1 g. of alumina, are plotted against the temperatures indicated by a thermocouple outside the catalyst tube (curve 1) and in the catalyst mass (curve 2). The liters of dimethyl ether contained in the gas are similarly shown in curves 3 and 4.

FIG. 2
Methanol over Zinc Oxide

The liters of gas and dimethyl ether at 20° and 740 mm, formed per hour by the passage of 50 cc of methanol over 1 g. of precipitated zinc oxide, are plotted against the temperature indicated by a thermocouple in the catalyst mass. A representative gas analysis is shown in the figure.

tion of dimethyl ether was almost negligible over this catalyst. The formation of simple gaseous products became prominent at about the same temperature as in the case of alumina. There was a considerable amount of blackening of the catalyst.

A series of experiments were conducted in which dimethyl ether was passed over the alumina catalyst along with varying amounts of water at temperatures from 270° to 430° . Six to nine liters per hour of dimethyl ether was passed over the catalyst. The results of a number of runs are given in Fig. 3, showing the variation with temperature of the amount of dimethyl ether

Fig. 3.
Hydration of Dimethyl Ether

The liters of dimethyl ether hydrated at various temperatures using various amounts of water with a flow of approximately seven liters of the ether per hour over 1 g. of an alumina catalyst are shown.

entering into reaction with varying amounts of water. It is apparent that the greatest amount of hydration took place when 8 to 10 cc. of water per hour was used. This corresponds to a 50% molecular excess of water, greater or lesser amounts of water decreasing the reaction. These results were obtained using 1 g. of alumina catalyst. When 6 g. of catalyst was used the maximum reaction was obtained with about 60 g. of water, i.e. 700% molecular excess per hour. The actual amount of ether hydrated per hour was approximately twice the amount hydrated over 1 g. of catalyst.

The water for the hydration was passed into the vaporizer in the same fashion as the alcohol in the dehydration experiments. The dimethyl ether was passed from a bottle under a light pressure and mixed with the steam just after it left the vaporizer. The amount of dimethyl ether reacting was determined by subtracting from the amount introduced the amount found in the gas, collected as in the dehydration experiments. As a check on this method the amount of methanol in the distillate was determined by the use of a Zeiss immersion refractometer. In general this showed 75 to 80% as much methanol as corresponded to the dimethyl ether disappearing.

Dimethyl ether was prepared in quantity by passing methanol over alumina at 340° , passing the products thru a condenser and receiver surrounded by ice water, and then absorbing the gas in conc. sulfuric acid. 100 cc. of sulfuric acid will satisfactorily absorb the ether until the volume is 400 cc. The slightly brown solution may be kept at room temperature and pressure. A water-white solution may be obtained by carrying out the absorption at 0° . When a supply of 10 or 12 liters of the ether was needed, 30 cc. of the solution in acid was placed in a $8\frac{1}{2}'' \times 1\frac{1}{3}''$ test tube and water slowly added until the tube was three fourths full. The evolved gas was collected over water. About 50% of the dissolved ether is liberated during the addition of the water and the remainder upon heating the solution to boiling in an oil bath for a few minutes.

Summary and Conclusions

The relation of temperature to the rate of dehydration of methanol over an alumina catalyst has been shown. There is a very small amount of decomposition of the ether between 350° - 380° . Decomposition increases rapidly above that point.

Zinc oxide precipitated as the hydroxide is very inactive towards methanol at 325° and induces a negligible ether formation at any temperature. At temperatures above 325° zinc oxide shows a rapidly increasing tendency to decompose methanol.

The optimum concentration of water for maximum hydration of dimethyl ether at a constant rate of flow is shown to vary with the amount of catalyst.

Madison, Wisconsin.

STUDIES IN HOMOGENEOUS GAS REACTIONS I

BY LOUIS STEVENSON KASSEL

Introduction

During the last few years the theory of activation by collision, rather than by radiation, has made rapid strides. Subsequent to the suggestion of activation by radiation by Perrin,¹ Lindemann² showed that on the basis of the simple radiation hypothesis the inversion of sucrose must be enormously accelerated by sunlight, in disagreement with experiment. Many other cases are now known in which the frequency which is calculated from the simple radiation hypothesis is quite without effect on a system; frequently it falls in a region in the infra-red which is not absorbed at all. At about the same time, Langmuir³ pointed out that there is not enough radiant energy in a system to account for the observed rates of reaction. Also, Lindemann⁴ called attention to the fact that, if the rates of activation and de-activation are large compared to the rate of reaction, the reaction may be kinetically unimolecular regardless of the order of the activation process. Calculations have been made by Christiansen and Kramers,⁵ by G. N. Lewis,⁶ and by Tolman⁷ which deal with the maximum possible rates of activation by radiation and by collision. In all of these calculations it was found necessary to make rather undesirably liberal assumptions to account for the observed rates of reaction; it cannot be said that they were very favorable to either method of activation.

Since these last-mentioned calculations were published, two distinct arguments in favor of activation by collision have appeared. The first of these is of an experimental nature; Hinshelwood and his co-workers⁸ have found that the decompositions of propaldehyde, of diethyl ether, and of dimethyl ether, all of which are strictly unimolecular at high pressures, deviate from the unimolecular course at low pressures, the specific reaction rate becoming smaller with decreasing pressure; Ramsperger⁹ has observed the same type of decrease in the specific rate in the decomposition of azomethane, and to a greater extent than in any of the cases studied by Hinshelwood. This decrease in the specific rate with decreasing pressure removes the very feature of unimolecular reactions which the radiation hypothesis was invented to explain.

and may be regarded as experimental evidence that radiation alone is not sufficient to cause the thermal decompositions of the above-mentioned substances. The second of these arguments in favor of activation by collision is based upon the suggestion made by Christiansen¹⁰ that the number of degrees of freedom of the molecule must be considered. This idea has been the basis for calculations by Hinshelwood¹¹ and by Fowler and Rideal¹² which show that the maximum rate of activation is very much increased by this assumption. In the paper by Fowler and Rideal there are some other assumptions made as to the method of activation which seem rather questionable, and which have been criticized by Tolman, Yost, and Dickinson.¹³ The treatment given by Hinshelwood seems to be preferable, and will be discussed in a later section. It may be said that as a result of this treatment it proves possible to account fairly well for the experimental results of Hinshelwood himself, but that the much faster decompositions of azomethane and of nitrogen pentoxide would require the assumption of an absurd number of degrees of freedom. Hinshelwood assumed that the specific reaction rate of all activated molecules was a constant, independent of their energy content. In this paper the consequences of replacing this assumption by the more reasonable one that the specific reaction rate for active molecules increases with their energy content will be considered. Just before the paper was submitted, an article appeared by Rice and Ramsperger¹⁴ in which this same assumption was made. The development and the final result are in many respects similar to that presented here, but there are enough differences to make publication of this article seem desirable.

The Energy of Activation

There seems to be some disagreement in the literature about the meaning to be given to the energy of activation. In the original Arrhenius equation,

$$\frac{d \ln K}{dT} = \frac{q}{RT^2},$$

q is the energy per mol necessary for activation, that is, the difference between the average energy of the activated molecules and the average energy of all the molecules. Tolman¹⁵ as the result of a rigorous and very general derivation, has obtained the expression

$$\frac{d \ln K}{dT} = \frac{\bar{\bar{E}} - \bar{E}}{kT^2},$$

¹³ Proc. Nat. Acad. Sci., 13, 188 (1927).

¹⁴ J. Am. Chem. Soc., 49, 1617 (1927).

¹⁵ J. Am. Chem. Soc., 47, 2652 (1925); "Statistical Mechanics," 265 (1927).

where $\bar{\bar{E}}$ is the average energy of the molecules that react and \bar{E} is the average energy of all the molecules; this equation applies to unimolecular reactions in which the equilibrium quota of activated molecules is essentially maintained; for other cases, Tolman's paper must be consulted. Tolman, then, proposes to call this quantity $\bar{\bar{E}} - \bar{E}$ the energy of activation. Lewis,¹⁶ on the other hand, defines the energy of activation as the minimum internal energy that a molecule must have in order to react; this definition does not involve any equation. This definition seems preferable to that of Tolman, because many simple hypotheses as to the nature of the activated states give values of $\bar{\bar{E}} - \bar{E}$ which are not constant with respect to the temperature; it should certainly be a fundamental requirement for any definition of the energy of activation that it be independent of the temperature.

Thus, for the simple case characterized by two internal degrees of freedom for the molecule, and maintenance of the equilibrium quota of activated molecules, Lewis¹⁷ has calculated the temperature coefficient of the reaction rate, assuming, (a), that the specific reaction rate of activated molecules is independent of their energy content, and, (b), that the specific reaction rate is proportional to the excess energy over some critical amount, E_0 . Assumption (a) leads to the equation

$$-\frac{d \ln K}{dT} = \frac{E_0}{kT^2},$$

while (b) gives

$$\frac{d \ln K}{dT} = \frac{E_0 + kT}{kT^2}.$$

These same results might have been obtained directly from Tolman's equation. Thus for the first case

$$\bar{\bar{E}} = \frac{\int_{E_0}^{\infty} N k T e^{-E/kT} E dE}{\int_{E_0}^{\infty} N k T e^{-E/kT} dE} = E_0 + kT,$$

and

$$\bar{E} = \frac{\int_0^{\infty} N k T e^{-E/kT} E dE}{\int_0^{\infty} N k T e^{-E/kT} dE} = kT$$

¹⁶ Lewis and Smith: *J. Am. Chem. Soc.*, **47**, 1512 (1925).

¹⁷ Lewis and Smith: *J. Am. Chem. Soc.*, **47**, 1513 (1925).

in the case of some of the faster reactions, notably the decompositions of azomethane and nitrogen pentoxide, without assuming an unreasonable number of degrees of freedom.

A second theory was then developed, based upon the following argument. In a complex molecule it is not sufficient to have a large amount of energy stored to cause decomposition. It is necessary for this energy, or a sufficient part of it, to be concentrated at some weak point in order to rupture the molecule. Now the simplest possible assumption is that there is some single bond in the molecule which is easier to break than any of the others, and that all but an inappreciable part of the reaction is initiated by a break of this bond. Then, if we assume that the bond breaks whenever it acquires energy in excess of some critical amount, E_0 , it should be possible to calculate from statistical mechanics a relation between the specific reaction rate of activated molecules and their energy content.

This differs from Theory II of Rice and Ramsperger in one way: they assumed that it was necessary for the energy E_0 to be concentrated in a single degree of freedom; the author has regarded a chemical bond as similar to a simple oscillator, and hence possessing two degrees of freedom. Save for the differences resulting directly from this one variation, the two developments are very similar.

Following Rice and Ramsperger, let a molecule of Class A be one whose total internal energy is between E and $E + dE$, and a molecule of Class C be one which is of Class A and in which some particular bond (that is, some particular *two* degrees of freedom) has energy in excess of E_0 . We assume that the rate at which molecules of Class A enter Class C is proportional to the fraction of the molecules of Class A which, *at equilibrium*, would belong to Class C. The assumptions involved in this are very clearly outlined by Rice and Ramsperger on page 1622 of their article, and are exactly the same in this theory as in theirs.

We wish, then, to determine the fraction of all molecules which have energy between E and $E + dE$ and which would have also, if the distribution law held, energy in excess of E_0 in some definite two degrees of freedom.

This calculation may be made in a way analogous to that used by Rice and Ramsperger. It may also be done in a different way, somewhat more elegant mathematically; a similar method is not available for the case treated by Rice and Ramsperger, because of the non-integrability of one of the equations. It is this second method which will be given here.

For a single oscillator it is well known that the probability of energy in the range from E to $E + dE$ is

$$P_{1,E,dE} = \frac{1}{kT} e^{-E/kT} dE,$$

and that the probability of energy greater than E is

$$P_{1,E} = e^{-E/kT}.$$

Then it follows at once that the probability that a system of two oscillators will have energy greater than E is

$$P_{2,E} = \int_0^E \left[\left(\frac{1}{kT} e^{-E_0/kT} dE_0 \right) \left(e^{-\frac{E-E_0}{kT}} \right) \right] + e^{-E/kT}$$

$$= \left(\frac{E}{kT} + 1 \right) e^{-E/kT}$$

In this expression the first term within the brackets is the probability that a chosen one of the oscillators will have energy in the range E_0 to $E_0 + dE_0$ and the second term is the probability that the other will have energy greater than $E - E_0$, so that the two together will have energy greater than E . The integral of this product from $E_0 = 0$ to $E_0 = E$ plus the probability that the first oscillator will have energy greater than E , is evidently the total probability that the two together will have energy greater than E .

It is then easy to find the probability that the two oscillators together will have energy in the range from E to $E + dE$. This is

$$P_{2,E,dE} = - \frac{\partial P_{2,E}}{\partial E} dE$$

$$= \frac{E}{(kT)^2} e^{-E/kT} dE.$$

Continuing in this way, it is found that the probability that S oscillators have energy greater than E is

$$P_{S,E} = \int_0^E \left\{ \left[\frac{1}{kT} e^{-E_0/kT} dE_0 \right] \left[\frac{1}{(S-2)!} \left(\frac{E-E_0}{kT} \right)^{S-2} + \dots + \right. \right.$$

$$\left. \left. \frac{E-E_0}{kT} + 1 \right] e^{-\frac{E-E_0}{kT}} \right\} + e^{-E/kT} \quad (1)$$

$$= \left[\frac{1}{(S-1)!} \left(\frac{E}{kT} \right)^{S-1} + \dots + \frac{1}{1!} \left(\frac{E}{kT} \right) + 1 \right] e^{-E/kT}$$

and the probability that they have energy in the range from E to $E + dE$ is

$$P_{S,E,dE} = - \frac{\partial P_{S,E}}{\partial E} dE$$

$$= \frac{E^{S-1}}{(S-1)! (kT)^S} e^{-E/kT} dE$$

These are of course all well-known results. Evidently the integrand of (1), namely,

$$C_{S,E,E_0,dE_0} = \left[\frac{1}{kT} e^{-E_0/kT} dE_0 \right] \left[\frac{1}{(S-2)!} \left(\frac{E-E_0}{kT} \right)^{S-2} + \dots + \frac{1}{1!} \frac{E-E_0}{kT} + 1 \right] e^{-\frac{E-E_0}{kT}}$$

is the probability that some chosen one of the S oscillators will have energy in the range E_0 to $E_0 + dE_0$ and that the whole group will have energy greater than E . Hence the probability that the whole group will have energy in the range E to $E + dE$ and that the chosen one will have energy in the range E_0 to $E_0 + dE_0$ is given by

$$\begin{aligned} C_{S,E,dE,E_0,dE_0} &= - \frac{\partial C_{S,E,E_0,dE_0}}{\partial E} dE \\ &= \frac{1}{(S-2)!} \frac{(E-E_0)^{S-2}}{(kT)^S} e^{-E/kT} dE dE_0. \end{aligned}$$

But it has already been found that the probability that the whole group will have energy in the range from E to $E + dE$ is

$$P_{S,E,dE} = \frac{E^{S-1}}{(S-1)! (kT)^S} e^{-E/kT} dE.$$

Hence the probability that when the S oscillators have energy in the range E to $E + dE$ some chosen one of them has energy in the range from E_0 to $E_0 + dE_0$ is

$$C_{S,E,dE,E_0,dE_0}^I = \frac{C_{S,E,dE,E_0,dE_0}}{P_{S,E,dE}} = \frac{(S-1)(E-E_0)^{S-2}}{E^{S-1}} dE_0.$$

Then, finally, the probability that when the whole group has energy in the range E to $E + dE$ some chosen one of them has energy greater than E_0 is

$$C_{S,E,E_0}^I = \int_0^E C_{S,E,dE,E_0,dE_0}^I = \left(\frac{E-E_0}{E} \right)^{S-1}$$

Hence the specific reaction rate of molecules with energy E is

$$A \left(\frac{E-E_0}{E} \right)^{S-1}.$$

where A is the proportionality constant.

It only remains to evaluate this constant in terms of the rate at high pressures. When the equilibrium quota of activated molecules is maintained, the number of molecules with energy between E and $E + dE$ that decompose per second is

$$N K_E dE = \left[\frac{N E^{S-1}}{(S-1)! (kT)^S} e^{-E/kT} dE \right] \left[A \left(\frac{E - E_0}{E} \right)^{S-1} \right]$$

where N is the total number of molecules. Then the total number of molecules that decompose per second is

$$N K_\infty = \int_{E_0}^{\infty} N K_E dE = N A e^{-E_0/kT}$$

Hence the observed specific reaction rate at high pressures will be

$$K_\infty = A e^{-E_0/kT}.$$

That is,

$$A = K_\infty e^{+E_0/kT},$$

and hence the specific reaction rate of activated molecules of energy E is

$$K_\infty e^{E_0/kT} \left(\frac{E - E_0}{E} \right)^{S-1}$$

This is the quantity that Rice and Ramsperger have called b_E ; the corresponding equation in their theory is (18); it is

$$b_E = K_\infty \frac{\Gamma\left(\frac{n}{2}\right)}{\Gamma\left(\frac{n+1}{2}\right)} e^{E_0/kT} \left(\frac{E - E_0}{kT} \right)^{\frac{1}{2}} \left(\frac{E - E_0}{E} \right)^{n/2-1}$$

It is of interest to calculate $\bar{\bar{E}}$ and \bar{E} in Tolman's equation

$$\frac{d \ln K}{dT} = \frac{E - E_0}{kT^2}$$

Evidently

$$\begin{aligned} \bar{\bar{E}} &= \frac{\int_{E_0}^{\infty} (E - E_0)^{S-1} E e^{-E/kT} dE}{\int_{E_0}^{\infty} (E - E_0)^{S-1} e^{-E/kT} dE} \\ &= E_0 + S k T \end{aligned}$$

$$\text{and} \quad \bar{E} = \frac{\int_0^{\infty} E \cdot E^{S-1} e^{-E/kT} dE}{\int_0^{\infty} E^{S-1} e^{-E/kT} dE} = S k T.$$

$$\text{Hence} \quad \bar{\bar{E}} - \bar{E} = E_0.$$

and

$$\frac{d \ln K}{dT} = \frac{E_0}{kT^2},$$

as could have been seen directly.

Thus if the assumption made by Rice and Ramsperger that reaction occurs whenever some single degree of freedom in the molecule acquires energy in excess of E_0 be replaced by the very similar assumption that reaction occurs whenever some bond (two degrees of freedom) in the molecule acquires energy in excess of E_0 , a slightly simpler, but very similar result is obtained for the specific reaction rate of activated molecules. If it is remembered that S in the present theory is equal to $n/2$ in the notation of Rice and Ramsperger, since the number of degrees of freedom is twice the number of oscillators, it is evident that the difference is in the direction of a relatively greater specific reaction rate for the molecules of high energy in the Rice and Ramsperger theory than in that of the author; this effect, however, is not a large one.

The Rate of Activation of Molecules

The next problem is to find the actual reaction rate when the pressure is not so high that the equilibrium quotas of activated molecules are maintained. If, following Hinshelwood and Rice and Ramsperger, we assume that at all temperatures and pressures the rate of activation is equal to the rate at which activated molecules would participate in collisions if the equilibrium quota of them were present, we may again use part of Rice and Ramsperger's derivation. They have shown that

$$K = \int_{E_0}^{\infty} \frac{W_E b_E dE}{1 + b_E k T / (ap)}$$

where $W_E dE$ is the equilibrium quota of molecules with energy between E and $E + dE$, b_E is the specific reaction rate of these molecules, and

$$a = 4 \sqrt{\frac{\pi k T}{m}} \sigma^2.$$

Here we have

$$W_E = \frac{1}{\gamma(S) (kT)^S} E^{S-1} e^{-E/kT},$$

and

$$b_E = A \left(\frac{E - E_0}{E} \right)^{S-1}$$

When these substitutions are made, the resulting equation reduces to

$$\frac{K}{K_\infty} = D \int_0^\infty \frac{e^{-x/RT} dx}{\frac{1}{x^{S-1}} + \frac{A/BN}{(x + E_0)^{S-1}}},$$

where $D = \frac{1}{\Gamma(S) (kT)^S}$ and $B = 4 \sqrt{\frac{\pi RT}{M}} \sigma^2$,

a form which is suitable for calculation. It is not possible to perform the integration algebraically, and it is thus necessary to obtain numerical values by graphical means or by quadratures.

Test of the Theory

The data of Ramsperger on the decomposition of azomethane afford the best test of any theory which concerns itself with the decrease of reaction rate with pressure, since the reaction has been studied at pressures low enough to give a very considerable decrease, *at two temperatures*. This last fact is of great importance, as will be seen.

The high-pressure measurements on azomethane may be fairly well represented by

$$\log K = 15.96512 - 11180.12/T,$$

or

$$K = 9.228 \times 10^{15} e^{-51130/RT}.$$

Comparison of this with the theoretical equation for high pressures shows that

$$A = 9.228 \times 10^{15},$$

and

$$E_0 = 51130.$$

Here E_0 and R are in calories per gram molecule. If it is assumed that

$$\sigma^2 = 5 \times 10^{-16} \text{ cm}^2$$

then

$$B = 5.214 \times 10^{-11}.$$

Then it only remains to select values for T and S ; for, when this has been done, D may be calculated, and K is thus expressed as a function of N only. The resulting integrals have been found by quadratures for a number of values of S and N . The results are summarized in the following tables.

$S = 6, T = 603$					
N	10^{23}	10^{22}	10^{21}	10^{20}	10^{19}
(P cm)	6.2×10^5	6.2×10^4	6.2×10^3	6.2×10^2	6.2×10
K/K $_{\infty}$.9162	.6528	.3055	.0937	.0193

$S = 9, T = 603$					
N	10^{21}	10^{19}	10^{18}	10^{17}	10^{16}
P	6200	62	6.2	.62	.062
K/K $_{\infty}$.7889	.2091	.06383	.01495	.002905

$S = 12, T = 603$					
N	10^{20}	10^{19}	10^{18}	10^{17}	10^{16}
P	620	62	6.2	.62	.062
K/K $_{\infty}$.8614	.5747	.3203	.1008	.03005

$S = 12, T = 563$					
N	10^{20}	10^{19}	10^{18}	10^{17}	10^{16}
P	580	58	5.8	.58	.058
K/K $_{\infty}$.9601	.6847	.3708	.1425	.04158

In considering these values several points are to be kept in mind. If the value of σ^2 is altered, it is not necessary to recalculate the integrals; new tables may be prepared from the ones given by reducing the values of N and P in the same ratio in which σ^2 has been increased; an inspection of the equation which governs K shows the correctness of this procedure. The values of A and E_0 used in this calculation are those obtained from the measurements in Ramsperger's first paper. It is likely that both A and E_0 are a little too small; the values of K_{∞} determined by extrapolation at 603° and 563° are 3.09×10^{-3} and 1.38×10^{-4} as compared with 2.66×10^{-3} and 1.28×10^{-4} as given by the equation. For this reason, in comparing observed and calculated values of the reaction rates, the comparison is made between values of K/K_{∞} and not between values of K; when this is done the error caused by inaccurate values of A and E_0 is small.

In Fig. 2 the calculated values of K/K_{∞} are compared with the experimental values. Here σ^2 has been taken as 1.5×10^{-14} , and the values of P given in the tables have been corrected accordingly. It is evident that the experimental results are fitted very well by taking $s = 12$, $\sigma^2 = 1.5 \times 10^{-14}$; they could be fitted equally well by a smaller value of s, in conjunction with a larger value for σ^2 . Thus, so far, the theory has proved satisfactory; but the real test is yet to come. It is now possible to calculate the specific reaction rate at any temperature and pressure, all of the arbitrary constants having been chosen. In Fig. 3 the theoretical curve for $T = 563$ is compared with the experimental one; the agreement is little short of remarkable.

Thus Ramsperger's results on the decrease in specific reaction rate with decrease in pressure may be quantitatively explained by taking $\sigma^2 = 1.5 \times$

10^{-14} , $S = 12$. They could be explained about as well, probably, by larger or smaller values of S , with correspondingly changed values of σ^2 . It may be advanced in criticism of this theory that the values chosen for S and σ^2 are both larger than is probable for such a molecule as azomethane. But it must be remembered that an activated molecule has a very high "internal temperature" and that many of the degrees of freedom that are normally frozen

FIG. 2

The lines are the theoretical curves for $s = 12$, $s = 9$, $s = 6$ respectively ($T = 603^\circ$, $\sigma^2 = 1.5 \times 10^{-14}$). A horizontal displacement of these curves corresponds to a change in the value of σ^2 . The points represent some of Ramsperger's experiments on azomethane at 603°K . A vertical displacement of these points corresponds to a change in the assumed value of K_∞ .

may be excited; thus the specific heat data would not be of value in fixing a value for s , since they apply to molecules with much lower internal energy. As for the value given for σ^2 , it must not be forgotten that this is the molecular diameter for collisional deactivation, which need not be the same as the diameter as determined by measurements of viscosity or thermal conductivity; indeed, the experiments of Stuart¹⁸ with mercury vapor have shown that in that case at least the diameter for collisional deactivation is about three times the normal kinetic theory diameter.

Three other unimolecular reactions are known in which the specific reaction rate decreases with decreasing pressure, the decompositions of propaldehyde, of diethyl ether, and of dimethyl ether. In Fig. 4 are given the

¹⁸ Z. Physik, **32**, 262 (1925).

plots of $\log K$ against $\log P$ for these reactions. For propaldehyde the curve is similar in form to the theoretical curves, but in order to reconcile the others with the theory it is necessary to assume that in the case of dimethyl ether the highest pressures used have been somewhat insufficient to give K while for diethyl ether the insufficiency must have been still greater. In order to decide this point, the reaction rate would need to be measured for these sub-

FIG. 3

The curve is drawn for $s = 12$, $\sigma^2 = 1.5 \times 10^{-14}$, $T = 563^\circ$. The points are some of the experimental results on azomethane at 563°K .

stances at pressures up to about five atmospheres. Unless it should be proved that the reaction rate does not increase further with increasing pressure, none of these results can be considered to be in disagreement with the theory.

The only other unimolecular reaction which has been studied at low pressures is the decomposition of nitrogen pentoxide. It seems wise to refrain from theories of this reaction until it has been further studied experimentally. If the rate actually does increase at very low pressures, in the way found by Hirst and Rideal¹⁹ it is probably because some other mechanism of reaction is becoming the dominating factor. Until more is known about this phase of the reaction it is useless to guess what this low-pressure reaction is like. Even the maintenance of the rate down to pressures of about .1 cm is hard

¹⁹ Proc. Roy. Soc., 109A, 526 (1925).

to account for. A rough calculation was made, taking $S = 7$, $\sigma^2 = 10^{-14}$ and $T = 300$. The results were

P	1500	15	.15	.0015
K/K _∞	.994	.891	.249	.0178

FIG. 4

The points give some of the experimental data for propaldehyde at 849° (I) and at 796° (II), for diethyl ether at 798° (III), and for dimethyl ether at 777° (IV). The ordinates are $\log K$, the distance between the horizontal lines being .5 unit, but the relative vertical positions of the curves are not significant.

Thus at a pressure of .15 cm the reaction rate has fallen to a fourth of its high pressure value. Hence it would be necessary either to take s greater than 7, or to assume a molecular diameter of more than 10^{-7} to account for the experimental results.

Discussion

The results which have been presented here seem to show that the simple type of theory which assumes a single specific reaction rate for all molecules is not satisfactory; this is the theory that Rice and Ramsperger have called

Theory I. Of the four reactions now known in which the specific reaction rate decreases with decreasing pressure, only the decomposition of propaldehyde was known to show this decrease at the time Rice and Ramsperger submitted their paper, and the experiments on this substance have not been extensive enough to reveal the inadequacy of the simple theory. But when it is attempted to apply this theory to the decompositions of diethyl and dimethyl ethers, and of azomethane, it is found unsatisfactory; this is shown by the curves of Fig. 1, which should be straight lines if Theory I is correct. There is every reason to believe that, if the experiments on propaldehyde were extended to lower pressures, here too the $1/K$, $1/P$ plot would curve.

It thus appears necessary to resort to a theory in which the specific reaction rate increases with the energy; there are now two such theories available, the one developed by Rice and Ramsperger, and called by them Theory II, and the one presented here, which may be called Theory III. These two are very similar: in the development of Theory II it is assumed that decomposition takes place whenever some single degree of freedom in the molecule acquires energy in excess of a critical amount; in Theory III, it is assumed that it is some particular bond (two degrees of freedom) rather than some single degree of freedom which must acquire the critical energy. In the development of the theories certain simplifying assumptions have been made. The discussion of these assumptions which Rice and Ramsperger have given is so good that it seems useless to consider them further here; the same assumptions occur in both theories.

It seems to the author that the physical basis for Theory III is perhaps a little better than for Theory II; rupture of the molecule might be expected to follow at a bond of the critical energy, and a bond represents *two* degrees of freedom. But such arguments are not conclusive and a decision between the two must rest upon experimental evidence. It is to be hoped that in the near future Rice and Ramsperger will attempt to apply their theory to azomethane. It is possible that the two theories will prove sufficiently different to decide between them by a careful application to this reaction.

As to the details of the theories, there is a considerable chance for change. It may be possible to avoid some of the assumptions that have been made, particularly in the calculation of b_E , but this would not be expected to produce any considerable change; the rotational energy might be more explicitly considered, though this would probably be very difficult, or a quantum treatment might be given. None of these changes could modify the general character of the theory.

Summary

1. Reasons have been adduced in support of the definition of energy of activation, due to G. N. Lewis, as the minimum internal energy which molecules must have in order to react.

2. It has been shown that the theory treated by Hinshelwood, and further developed by Rice and Ramsperger, which these authors have called Theory I, in which it is assumed that all activated molecules have the same specific reaction rate, regardless of their energy content, is in disagreement with the experimental results for the decompositions of diethyl ether, dimethyl ether and azomethane.

3. On the basis of statistical mechanics an expression has been deduced for the variation of the specific reaction rate of activated molecules with their energy content.

4. By the use of this expression, an equation has been derived which gives the specific reaction rate for a unimolecular reaction at any pressure.

5. This equation has been shown to be in quantitative agreement with the experimental results for the decomposition of azomethane.

6. The differences between this theory and the similar one just published by Rice and Ramsperger (Theory II) have been pointed out.

Note added in proof: Attention is specially called to the fact that the term degree of freedom is used in this paper in the same sense as it has been used by Rice and Ramsperger. This disagrees with the customary usage, according to which an oscillator has only a single degree of freedom, although it possesses both kinetic and potential energy. As the term is used here, an oscillator has two degrees of freedom.

It is evidently necessary to discuss in more detail the theory of Fowler and Rideal (ref. 12). It was pointed out by Tolman, Yost and Dickinson (ref. 13) that this theory required very large diameters for collisional deactivation to account for the reaction rate of nitrogen pentoxide. It has since been shown by Bernard Lewis²⁰ that there is a numerical error in these calculations, and that the necessary diameters are not as large as Tolman, Yost and Dickinson had supposed. They are, however, very large; to make the rate of production of activated molecules equal to the rate of reaction at 300° K. and a pressure of .05 mm., it is necessary to assume a diameter of 6×10^{-6} cm, which is certainly very large. A still larger diameter would be necessary to maintain the reaction rate at its full value at this pressure, and this is necessary, since the recent work of Hibben²¹ shows that the rate is surely maintained at a pressure of .03 mm. and probably at one ten-fold lower. Lewis's suggestion that this large diameter is "apparent and not real" and that if we take into account the fact that every collision involving an activated molecule does not result in its destruction we will find smaller deactivational diameters, seems to the author to be entirely incorrect. We can calculate the necessary rate of production of activated molecules from the rate of reaction. If we set this equal to a rate of collisional deactivation, we get a number of collisions from which

²⁰ Science, **66**, 331 (1927).

²¹ Proc. Nat. Acad. Sci., **13**, 626 (1927).

we calculate a diameter; but if only some of the collisions are effective, since the number of effective ones is prescribed for us, we must have more collisions altogether, and hence larger diameters. The idea of a target area is one to which the author subscribes, but it cannot lead to decreased diameters.

Lewis has made calculations for azomethane²² similar to those for nitrogen pentoxide and has, remarkably enough, succeeded in accounting for a rate of activation so large as to permit of the maintenance of specific rate in this reaction at pressures much lower than those at which Ramsperger subsequently found the rate was not maintained.

THE CATALYTIC DECOMPOSITION OF SODIUM HYPOCHLORITE SOLUTIONS*

I. Mechanism of the Reaction

BY JOHN R. LEWIS

Until recently no systematic study of the catalytic decomposition of sodium hypochlorite solutions had been carried out. In 1923 and 1926, however, articles by Howell¹ and Chirnoaga² were published in which appeared their results using cobalt peroxide as catalyst. Howell assumed that the decomposition rate follows the unimolecular law; but pointed out that the constant (K) increases as the reaction proceeds. He showed that the rate increases in the presence of sodium ions while hydroxyl ions have the opposite effect. Chirnoaga, on the other hand, obtained more concordant results by using the equation $-dc/dt = Kc^{1/n}$ (where c is the concentration, t the time in minutes, K and n constants). This is especially true in those cases where the catalyst was very active. In other cases, i. e. where the catalyst was less active the unimolecular law held. In general the work of the above mentioned investigators has been confirmed in this laboratory but it appeared that the mechanism of the decomposition can be explained more simply by using the equation $dc/dt = K$; for when the volume of the evolved oxygen, in cubic centimeters, was plotted against the time, in minutes, a straight line was obtained. This linear relationship held in most cases from ten to twenty percent of the total reaction.

These results suggested a mechanism similar to that found by Armstrong³ and by Armstrong and Hilditch⁴ for the hydrolysis of sugar solutions by enzymes and for the hydrogenation of certain unsaturated organic esters using nickel as catalyst. In the paper⁵ on the action of enzymes on sugar it was shown that equal quantities of sugar were hydrolyzed in equal time intervals. A similar relationship was obtained in the hydrogenation experiments. While the linear portion of the curve covered approximately ten percent of the total reaction in the case of the sugar hydrolysis, the linear portion of the curve in the hydrogenations held fairly well from fifty to eighty percent of the total reaction. Among other examples of reactions of this type may be mentioned the results of Bredig and von Berneck⁶ who found that $dc/dt = K$ for the decomposition of hydrogen peroxide by colloidal platinum, and also the experiments of Hinshelwood⁷ on the decomposition of certain gases at the sur-

faces of hot wires. Reactions of this type are usually spoken of as zero order reactions.

The conditions necessary for the realization of zero order reactions may be stated as follows:

1. Comparatively high concentration of the substance undergoing change.
2. The catalyst should maintain its activity.
3. There should be small quantities of catalyst in order that the active mass, i. e. the adsorbed reactant on the catalyst is small compared with the bulk of reactant.
4. The decomposition of the reactant-catalyst complex must be the slow reaction, thus insuring at all times a catalyst surface completely covered with reactant.

Experimental

Preparation of Materials:

1. Sodium hypochlorite solutions were prepared as follows: Approximately normal sodium hydroxide, prepared by the action of metallic sodium on distilled water, was treated with pure chlorine. The gas was allowed to bubble slowly through the sodium hydroxide solution, the container of which was kept cool by immersion in an ice bath. The progress of the reaction was determined from time to time by pipeting out two cubic centimeters of the solution, destroying the sodium hypochlorite by means of neutralized hydrogen peroxide, and titrating the excess alkali with standard acid. The reaction was stopped when the hypochlorite solution contained but a slight excess of free sodium hydroxide. The sodium hypochlorite was determined by adding a known quantity of the solution to an acidified potassium iodide solution, and titrating the freed iodine with standardized sodium thiosulfate. The initial concentrations of the hypochlorite solutions prepared are as follows:

Solution	Concentration of NaClO	Concentration of NaOH
1	29.74 gr. per L	0.13 Normal
2	37.76 gr. " "	0.03 " "
3	56.48 gr. " "	0.11 " "
4	46.55 gr. " "	0.032 " "

2. The catalysts solutions were made from recrystallized salts; standard stock solutions of copper sulfate, ferric sulfate and cobalt sulfate being made. The cobalt peroxide, copper oxide, and iron oxide suspensions were made according to the method of Howell¹ and Chirnoaga² except that the precipitated oxides were washed by decantation in every case rather than by filtering. This process was continued until the wash water was practically free from alkali, requiring in some cases three or four weeks.

¹ Howell: Proc. Roy. Soc., 104A, 134 (1923).

² Chirnoaga: J. Chem. Soc., 1926, 1693.

Apparatus and Method of Experimentation

The apparatus used for the first experiments was essentially the same as that devised and used by Walton¹ and his students for their studies in chemical kinetics. Twenty-five cubic centimeters of the sodium hypochlorite and the catalysts (usually 1 c.c.) were placed in especially designed reaction flasks supported by a shaking device in a thermostat. The catalyst was either placed in a glass capsul held in the neck of the flask until the desired moment, when it was allowed to fall into the hypochlorite solution; or pipeted directly into the reaction flask through a short side-neck which was immediately closed. At the instant the catalyst was mixed with the hypochlorite, a stop-watch and the shaker were started. Readings of the evolved oxygen, collected in water-jacketed burets, were taken at suitable intervals of time until the reaction was complete.

Calculations

The data for tabulation in the tables which follow were obtained by the following equations. Equation (1) is the so-called zero-order equation, equation (2) the ordinary unimolecular expression, and (3) which is one form of the well known Freundlich Adsorption equation used by Chirnoaga¹ in his hypochlorite studies.

$$(1) \quad K = dx/dt \text{ or more simply } K = x/t$$

where x is the c.c. of oxygen evolved in time (t) expressed in minutes.

$$(2) \quad K_1 = \frac{2.303}{t} \log \frac{C_0}{C_0 - C_t}$$

where t is the time in minutes, C_0 is the concentration of hypochlorite expressed in cubic centimeters of oxygen at zero time, and C_t is the concentration after time t .

$$(3) \quad K_2 = \frac{1}{t} \frac{(C_0^{N-1} - C_t^{N-1})N}{N-1}$$

where C_0 and C_t and t are the same as in (2) and N is a constant.

Preliminary Results

The effect of the rate of shaking of the reaction mixture on the rate of oxygen evolution was determined. The following table gives the results.

TABLE I

Experiment Number	Number of shakes per minute	c.c. of oxygen after 20 minutes	K
1	400	4.3	0.215
2	630	6.6	0.33
3	800	8.15	0.407
4	1190	8.1	0.405

¹ Walton: *Z. physik. Chem.*, **47**, 185 (1904).

It will be observed that the values for the last two agree well, showing that rates of 800 or above give concordant results. All subsequent experiments were carried out with the rate of shaking at 800 or more per minute.

It was found that glass or Bakelite beads placed in the reaction flasks to prevent supersaturation, retarded the reaction rate. This was caused in the

case of the Bakelite by a chemical reaction between the hypochlorite and the Bakelite. The glass beads cut down the rate of hypochlorite decomposition by holding the catalyst particles mechanically on the bead surfaces.

Results

The results obtained using the above equations as a basis for calculating the rate of decomposition are given in the following tables. In order to conserve space, duplicate results (obtained in all cases) are not given.

Tables II and III are for cobalt peroxide at 45°C and 35°C, while Table IV is for cobalt sulfate solution. Tables V and VI give the results obtained for

copper sulfate solution and for precipitated copper oxide. Finally in Tables VII, VIII and IX are given the results for mixed oxides of iron and copper. In Tables IV, V, VII, VIII and IX the catalysts were added in the solution form. Due to the alkalinity of the hypochlorite solutions, the catalyst solutions reacted, forming the desired oxides. Data for the decomposition of the hypochlorite using precipitated iron oxide only are not given since the decomposition rate is so slow that it may be considered as without effect. In the tables (t), (x), (K), (K₁), and (K₂) have the same significance as in the equations. The data given in the tables are also presented graphically in Fig. 1.

Discussion

Upon examination of the above tables it will be noted that the values for $K = x/t$ remain fairly constant for a time but fall off after twenty or thirty percent of the reaction is completed. On the other hand values for K_1 , the unimolecular constant, increase as the reaction proceeds. This is true in all

cases. However in Tables VII, VIII and IX giving the data for mixed oxides of iron and copper it will be noted that K_1 falls after an initial increase. Upon examination of the values obtained by using equation (3) it will be apparent that the results are more concordant than those obtained using the unimolecular equation; but they also increase or decrease, paralleling the K_1 values.

It will be observed in Tables VII, VIII and IX that the mixed oxides show a marked "promoter effect" on the decomposition rate. K and K_1 values given in Table VII are good but those in Tables VIII and IX are somewhat irregular. It is proposed to extend this phase of the investigation.

The Decomposition of Sodium Hypochlorite Solutions when a Constant Fresh Supply of Hypochlorite was allowed to pass over a Fixed Amount of Catalyst.

In order to obtain more information concerning the mechanisms of the decomposition of sodium hypochlorite solutions, the following additional experiments were performed.

The apparatus shown in Fig. 2 was used for this work. The hypochlorite from a storage bottle was allowed to enter drop by drop into the inner vessel D through the tube B. The volume of the liquid in D being kept constant by holding its level at C. The hypochlorite passed through the sintered glass filter E and was collected in F. The pores of this filter¹ however were suffi-

FIG. 2

Apparatus used in measuring the decomposition of NaClO solutions.

¹ This apparatus was made from a Jena glass crucible obtained from the Empire Laboratory Supply Co., 218-220 E. 37th St., New York.

ciently small to prevent the passage of catalyst particles. The oxygen liberated passed through the tube A and was collected and measured in water-jacketed burets. The stirrer S operating at 550 revolutions per minute, worked through an ordinary mercury seal. The apparatus was immersed in a water bath at constant temperature.

In passing through this apparatus the hypochlorite solution changed in concentration from ten to twenty percent. The following tables give the results obtained. Cobalt peroxide, the only catalyst used in these experiments was of the same concentration as that used in Table II. Solutions used to obtain the data in Tables X, XI and XII were made by diluting the original stock solution with distilled water. The values given are for cubic centimeters of oxygen at 0°C and 760 mm. pressure; t , x and K having the notations used in the previous tables. C_1 refers to the initial concentration of the hypochlorite in grams per liter. Fig. 3 expresses the same results graphically.

Discussion

Examination of the data presented in Tables X, XI and XII and illustrated graphically in Fig. 3, shows that the rate of decomposition as measured by the equation $K = x/t$ is practically constant over a wide range of concentration. Results obtained with concentrations of 46.5 39.6 and 34.2 grams of sodium hypochlorite per liter being 0.271 0.273 and 0.270 respectively. When the concentration of the hypochlorite falls below these values K falls off.

By comparing the results in Tables X and XI it will be observed that the rate of reaction is proportional to the concentration of the catalyst, confirming the observations of Howell¹ and Chirnoaga.²

The temperature coefficient, determined over the range 30° C to 45° C is lower than that determined by Howell. However the value $K_{40}/K_{30} = 2.0$ obtained in the above described apparatus agree well with the value $K_{45}/K_{35} = 2.02$ obtained in the shaker apparatus.

¹ Howell: Proc. Roy. Soc., 104A, 134 (1923).

² Chirnoaga: J. Chem. Soc., 1926, 1693.

The normal temperature coefficient obtained for this reaction indicates that catalytic decomposition of sodium hypochlorite is chemical in nature. If it is assumed that the decomposition is due to the formation of a catalyst-hypochlorite complex and its subsequent decomposition, then the mechanism of the reaction can be pictured as hypochlorite ions or molecules combining with the catalyst forming the addition compound which immediately decom-

FIG. 3

Decomposition of hypochlorite solutions using apparatus shown in Fig. 2.

(1, 2) and (4) are for solutions containing 28.46, 39.6, and 39.6 gr. NaClO per liter using 1 cc. cobalt peroxide catalyst at 30°C .

(3) is same as (2) except 2 cc. of catalyst are used. (5) is same as (2) except the temperature was 40°C .

poses. Just as long as the concentration of the hypochlorite is relatively high in comparison with that of the catalyst, the decomposition will take place at a regular rate, for at the moment a catalyst-hypochlorite molecule decomposes another hypochlorite molecule combines with the catalyst, forming another complex which subsequently decomposes. After a time however the rate will fall off due to any one, or combination, of the following causes:

1. Change in the activity of the catalyst caused by changes in its surface.
2. Poisoning of the catalyst; in this case no doubt by hydroxyl ions.
3. A low concentration of the reactant in the solution surrounding the catalyst. Data obtained under such conditions usually fit the unimolecular equation or the Freundlich equation (3 above).

Summary

1. The mechanism of the decomposition of sodium hypochlorite solutions has been studied using cobalt, copper and iron oxides and peroxides as catalysts.

2. The data obtained have been given in tables and shown graphically.
3. It was shown that the decomposition takes place at a regular rate as long as the catalyst is completely covered with reactant.
4. An apparatus has been described suitable for experiments where a constant fresh supply of a reactant solution may be passed over a fixed amount of catalyst.

Madison, Wisconsin.

MOLECULAR ORIENTATION AT SURFACES OF SOLIDS

I. MEASUREMENT OF CONTACT ANGLE AND THE WORK OF ADHESION OF ORGANIC SUBSTANCES FOR WATER*

BY A. H. NIETZ

The study of solid surfaces has been taken up only recently and has not yet been given the attention it deserves. Some practical applications of the study of wetting power have been made in the flotation process, largely with minerals, of course. A few organic substances have been studied by Adam and Jessop,¹ who have calculated the work of adhesion of several organic solids. In recent years it has come to be realized that molecular orientation at interfaces (polarity of solid surfaces) is intimately connected with the phenomenon of adhesion and with the stability of colloids. The interfacial tension of gelatin and toluene² was shown in this Laboratory to support this view, and in order to obtain more quantitative information on this, Dr. Sheppard suggested to the author an experimental study of the "contact angle" of related organic compounds.

The method used has been known for many years but was never applied to any extent so far as known until the work of Adam and Jessop (*loc. cit.*). Young in 1805³ and Dupré⁴ in 1869 published some of the relations for the contact angle of a liquid against a solid and the work of adhesion between the two.

For the sake of clearness, the development of the method from the equation of Dupré and the work of Young is included here. If we have two bars, each 1 sq. cm., in cross-section, of liquid and solid respectively, represented by L and S in Fig. 1, the work done in separating L from S is

$$W = T_L + T_S - T_{LS}$$

where T_L and T_S are the free energies of the surfaces which have appeared and T_{LS} is the free energy of the interface which has disappeared. Consider next the relations for a drop of liquid L resting in equilibrium on a solid S (Fig. 2). At the point B, we have an equilibrium of forces represented by the equation

$$T_{SA} = T_{SL} + T_{LA} \cos \theta$$

where θ is the angle of contact between the liquid and solid as shown. This

$$W = T_L + T_S - T_{LS}$$

WORK OF ADHESION.

⁴ "Théorie mécanique de la Chaleur," p. 369 (1869).

equation can also be derived from purely theoretical considerations. If we now substitute this equation in the Dupré equation, we obtain

$$W = T_{LA} (1 + \cos \theta)$$

which is an expression easily applied to the work of adhesion. It is necessary to make but two measurements, T_{LA} , the surface tension of the liquid in contact with the solid; and θ , the angle of contact of water against the solid. This is the basis of the experimental procedure.

Experimental Methods

Two practical methods for the measurement of the contact angle have been used. One employs the rotating cylinder described by Ablett,¹ and the other the tilting plate as used by Adam and Jessop and others. The former uses material coated on a silver-plated cylinder, the angle being obtained by adjusting the height of liquid until the liquid-air boundary is straight right up to the line of contact. In the second method a plate was coated with the material and then inclined until the liquid-air interface was perfectly plane, the angle being

FIG. 2

measured directly. The second method offers decided advantages and is sufficiently accurate for ordinary work.

Differences due to unknown causes have been found between the two methods. Though some refinements in Ablett's apparatus have been made and the accuracy increased, his results have not been reproduced in every respect for paraffin, and some mysterious differences occur with other substances when measured by the two method. Time has not permitted a complete investigation which should be made of the causes for these differences.

An attempt was made to check Ablett's results with paraffin. The paraffin used represents a product of very high purity. It was prepared especially for this work by Dr. H. T. Clarke, the treatment consisting of repeated stirring with warm concentrated sulphuric acid, melting at about 100° for several hours in contact with metallic sodium, and final distillation in vacuo. The boiling point of the final product was 218° - 225° at 4 mm.

The results with this paraffin gave $109^\circ \pm 30'$ for the angle of contact in water, measured by Ablett's method, and the same by the plate method. This high value in itself would indicate a high degree of purity, i.e., freedom from unsaturated or polar compounds. Ablett's results were verified so far as two sets of values for clockwise and counter-clockwise rotation at various speeds are concerned. But it was not found possible to determine what he calls a "stationary angle," that is, an angle when there is no relative motion of solid with respect to liquid. It would seem next to physically impossible

¹ Phil. Mag., 46, 244 (1923).

to obtain this condition since in an apparatus of Ablett's type it would be necessary to add liquid at *exactly* the same rate as the advance of solid out of the liquid to prevent motion of solid into or out of the liquid. Ablett himself does not specify how these stationary angles could have been obtained. Merely allowing the cylinder to remain motionless and adding water would give a result in the same sense as the solid advancing into the water, or, in the present case, counter-clockwise motion. It is hoped later to make an at-

APPARATUS FOR MEASURING CONTACT ANGLE

FIG. 3

tempt to obtain the necessary condition for a stationary angle, but it is very doubtful that it can easily be secured. Further reference is made below to differences between the cylinder and plate method.

For the present work the plate method was found more rapid and convenient, and the results are believed more reliable, at least until the nature of certain discrepancies is better understood. A special form of apparatus was designed which is very convenient in use and eliminates to some extent the error involved in the motion of the solid in or out of the liquid. This is sketched in Fig. 3. The slide S is an ordinary microscopic slide on which is coated a small quantity of the melted solid. The slide is held by a convenient clamp C so that it can be turned to make various angles with the water as the disk D is turned. The height of the liquid in the jar J is so adjusted and the clamp C is so placed that the line of contact L is on the axis of rotation of the disk D. This disc has a carefully graduated metal scale affixed to its surface in such a way that it can be adjusted. When an adjoining pointer indicates zero degrees, the slide S should be in a horizontal position as shown by a small spirit level placed on it. The disk is mounted to the chuck of a small jeweller's lathe which permits smooth turning and accurate centering.

By the use of this apparatus, therefore, the angle as measured is relatively free from the large errors due to the liquid advancing or receding from the solid. Added advantage can be obtained by placing the jar in a small outer tray with a draining tube so that by providing a suitable source of supply,

pure water can be run continually into the jar J and overflow at the level of the line of contact so that the surface is automatically swept and renewed.

The jar J is a rectangular one, preferably with plate glass sides front and rear, such as an absorption cell for photometric work. A glass is ruled with black lines at intervals of about 3 mm. and is cemented to the rear surface. In place of this, a single fine black wire, held around the jar by means of a rubber band on one side, may be used. A small mirror is placed in front of the jar J at an angle. The height of the liquid is so adjusted that it is just up to the axis of rotation. The slide S is then tilted until the image of the straight lines, seen in the mirror, reflected from the under side of the liquid-air interface, appears perfectly straight right up to the line of contact. To facilitate this a ground glass and suitably bright electric lamp are placed on the far side of the jar.

The substances used throughout were Eastman Synthetic Organic Chemicals and of as high purity as is commercially obtainable. In several cases these were recrystallized. A sample of the substance to be used was melted in a small test tube and several drops allowed to crystallize on the end of a clean microscope slide.

Great precautions, of course, had to be taken to assure the cleanliness of all the glassware used and the purity of the water. Potassium dichromate cleaning solution was used on the glassware and the surface tension of the water was checked before every determination. This was done at first by means of a du Noüy tensiometer. It was found, however, that this could be done more conveniently and just as accurately by placing a slide of pure paraffin of known contact angle in the apparatus and reading the angle. A very slight difference of surface tension or contamination of any sort could be very easily detected by the lowering of the angle.

As previously inferred, the Ablett cylinder and the plate methods gave many widely divergent results, the cause of which is unknown and requires further investigation. Some of these discrepancies are shown in Table I.

TABLE I

Comparison of Contact Angle measured by Ablett Cylinder and by Plate Methods

	Cylinder		Plate
	Out	In	
Myristic acid	60	—	115
Palmitic "	54	36	111
Stearic "	53	91	106
Ethylene glycol dilaurate	76	94	123
" " distearate	56	64	75
Cellulose acetate	58	—	25
" nitrate	77	—	15
2-4-6 trichlor aniline	62	90	55

While in none of these measurements by either method was the surface of the water swept, it is to be noted that several of the above substances do not contaminate a water surface in the ordinary sense (lower the surface tension). Ethylene glycol dilaurate and distearate, and stearic acid, do not affect the surface tension. Because of erratic results obtained in a few cases with the cylinder, and because of the greater convenience and ease of measurement with the plate method, as well as the general consistency of the results obtained, the latter has been preferred for the present at least, and the measurements discussed below were all made in that way.

By use of overflow at the surface with the plate method as already suggested, the surface is swept continually, and if this is desired, the apparatus as illustrated is most convenient. However, unless contamination from a foreign substance is considered, and this is not likely under ordinary conditions of cleanliness, there is no particular advantage in sweeping the surface. Even though the material under examination lowers the surface tension by a large amount, the values of T and θ in the equation $W = T(1 + \cos \theta)$ are those under such conditions. As long as the solid is in contact with water, at any rate, sweeping will have no noticeable effect on the observed surface tension, unless, of course, the rate of solution is extraordinarily slow. If any foreign substance, however, is present, this will be swept away.

The plate method is more susceptible to foreign contamination than the cylinder. For example, pure paraffin was coated on a cylinder and turned on a lathe to give a smooth surface, and the same material was coated on a slide and scraped. The contact angle measured by the two methods with these specimens was in each case 108° . A very small fragment of cetyl alcohol was then dropped on the water in each case. Cetyl alcohol lowers the surface tension of water 50% . The contact angle was lowered from 108° to 96° with the cylinder method, and from 108° to 72° with the plate. No reason is known for this difference between the two methods.

Another objection to the cylinder method is the difficulty of measuring small angles. Unless the top surface of the water-air interface is used for reflection, and this is poor, giving a very faint image, the angle cannot be determined if it is much under 60° . Since many substances give angles from 30° to 60° measurements on them are best made by the plate method.

Results

Measurements here recorded for solids are, within limits of error, well in accord with other similar work for liquids and the more limited published results for solids. Harkins and his co-workers¹ have demonstrated quite clearly the existence of certain polar groups and their effect on the work of adhesion of liquids, as measured by the method of interfacial tension. Langmuir² has also put forth views which have experimental verification and which explain the effects of polar groups in producing molecular orientation.

¹ J. Am. Chem. Soc., **39**, 354 (1917); **42**, 700 (1920); **43**, 35 (1921).

² J. Am. Chem. Soc., **39**, 1848 (1917); Chem. Met. Eng., **15**, 468 (1916).

That the measurement for solids are comparable with results of Harkins for liquids is fairly well indicated by Table II. Comparisons are made for the substances of similar constitution which could be found in the measurements by the two methods. The results for liquids are calculated from the values of the surface tensions of the two liquids and the interfacial tension. Those for solids are based on the measurement of contact angle and surface tension of water in contact with solid.

In the case of benzene, caprylic acid, and undecylenic acid, measurements were made on both liquid and solid and in each case values for the liquid are higher. The general trend of the results for solids closely parallels those for liquids, however. Measurements of a series of solid homologues, or of solid compounds with similar terminal groups, show greater variations within the group than for a similar class in Harkins' data for liquids. This is seen by comparison of Table IV with some of Harkins' values for related compounds. In Table III are given a few of the latter for hydrocarbons, which as a whole show far less divergence than the hydrocarbons, in Table IV.

Table IV gives complete data on contact angle and work of adhesion for 70 organic solids. Values given are for the following:

Column 1	Contact angle, θ
Column 2	% reduction of the surface tension of water caused, T_R
Column 3	% reduction of the contact angle of pure paraffin θ_R
Column 4	notes on spreading
Column 5	Work of adhesion, W

Column 2 is expressed as a percentage and represents the lowering of surface tension of water in the presence of solid. Column 3 shows the percentage lowering of the contact angle of pure paraffin against water in the presence of the solid in question.

The data on spreading are only roughly quantitative and are expressed as

V violent
M moderate
S slight
N none

It is at once evident from Table IV that in each chemical class there is a rather wide range of values for the work of adhesion, W . There is also no tendency for any class to assume a particular value. This indicates of course that other factors than the mere presence of the better known polar groups influence the attraction for water. It is unfortunate that it is difficult to secure more comparisons, as can be done for liquids, between series of related compounds. Many of the substances needed are not solid at ordinary temperatures, and a great many are very difficult to prepare in any state of purity. Consequently, it will require time to secure even a moderate amount of data. Nevertheless, the figures of Table IV afford some interesting information.

Discussion for the present will be confined to work of adhesion only. Following are some of the comparisons which may be found in the table.

Benzene	43.5
Benzoic Acid	93.6

The carboxyl group causes a great increase in the work of adhesion, as expected. The measurements for benzene were made in the solid state, in water at 1°.

Naphthalene	106.3
β -Naphthol	128.5

The increase here is appreciable, though not large. A single phenolic hydroxyl group on the large naphthalene molecule already containing polar double bonds would probably not be able to exert much effect.

Two phenolic groups in the benzene ring, however, produce a very great change.

Benzene	43.5
Resorcinol (1:3OH)	137.8

A single phenolic group with an additional methyl group in thymol produces only a moderate increase.

Benzene	43.5
Thymol	65.5

The $-Cl$ radicle is shown as polar from the values for trichlorobenzene.

Benzene	43.5
1-2-4 trichlorobenzene	62.6

The alcoholic hydroxyl appears to have greater attraction for water than the carboxyl group. This is at least the case for two of the higher hydrocarbons, as shown by

Myristyl alcohol	54.2	Cetyl alcohol	61.3
Myristic acid	32.0	Palmitic acid	42.8

These values are put forward with reserve, since they seem inconsistent and these higher solid alcohols are purified with difficulty.

The effect of additional polar groups is again seen in values for two ethers.

Glycerol phenyl ether	$CH_2OH.CH$	$OH.CH_2OC_6H_5$	97.6
Diphenyl ether		$C_6H_5OC_6H_5$	75.7

Some interesting results are afforded by the following measurements on substituted methanes. The value for toluene is taken from Harkins' results for liquids but is inserted for comparison.

Benzene (solid)	43.5
Toluene (liquid-Harkins)	66.6
Diphenyl methane	103.6
Triphenyl "	123.4
Tetraphenyl "	140.0

The last value for tetraphenyl methane is not exact, the result lying between 140.0 and 145.6. The tetraphenyl methane was very kindly furnished by Dr. Edward Mack, Jr.

The differences between each member and the next of this series are

Benzene	
23.1	
Toluene*	
37.0	
Diphenyl methane*	
19.8	
Triphenyl	"
16.6	
Tetraphenyl	"

These indicate roughly a steady constant increase for each phenyl group added, the increase becoming less as the molecule becomes larger. They also show again the effect of the double bonds of the benzene ring.

The di- and tri-phenyl methanes show a result on cooling in contact with water which is not understood at present, it being mentioned only as a matter of record. This peculiar effect is illustrated by the following:

	Cooled in Air	Cooled in Contact with Water
Diphenyl methane	$\left\{ \begin{array}{l} \theta \quad 62^\circ \\ W \quad 104 \end{array} \right.$	$\left\{ \begin{array}{l} \theta \quad 93^\circ \\ W \quad 67 \end{array} \right.$
Triphenyl methane	$\left\{ \begin{array}{l} \theta \quad 46^\circ \\ W \quad 123.4 \end{array} \right.$	$\left\{ \begin{array}{l} \theta \quad 153^\circ \\ W \quad 7.9 \end{array} \right.$
Stearic acid (See Table V also)	$\left\{ \begin{array}{l} \theta \quad 106^\circ \\ W \quad 52.8 \end{array} \right.$	$\left\{ \begin{array}{l} \theta \quad 96^\circ \\ W \quad 65.2 \end{array} \right.$

The substituted methanes give results in the opposite sense from most substances cooled in contact with water, as, for example, stearic acid. That is, instead of the water producing increased work of adhesion through orientation of polar groups, it has produced less. In the case of triphenyl methane especially the change is tremendous, work of adhesion being reduced to approximately one-fifteenth by cooling on water. Conditions causing results in this direction might be the leaching-out of a very highly polar impurity, which we believe improbable, or an adsorption effect. At any rate we have not yet been able to investigate the matter further.

(Other results with aromatic hydrocarbons are the following:

Benzene	43.5
Naphthalene	106.3
Anthracene	68.6

The increase from benzene to naphthalene is seemingly accounted for by the addition of the second nucleus and the double bonds it contains. The decrease shown by anthracene over naphthalene might be explained by assuming some sort of folded configuration for the naphthalene molecule, but this is not borne out by the findings of Bragg¹ as to the x-ray crystal structure.

*The value for toluene is out of line, since, as previously stated, a liquid gives a higher result than the same substance in solid form.

¹ Proc. Phys. Soc., 34, 33 (1921); 35, 167 (1923).

Consequently we are again confronted by facts difficult to explain. It seems possible that in some of these cases consideration should be given to the structure of the crystal aggregate rather than to the individual molecule alone.

Another case in which configuration may play a part is:

Diphenyl	99.6
Naphthalene	113.7

Mack¹ has shown that diphenyl has a "collapsed" or folded structure. The molecule consists of two benzene nuclei face to face. Consequently the residual valences are probably quite completely satisfied within the molecule itself. Naphthalene has a more extended configuration, and four of the double bonds are effective in increasing the work of adhesion.

FIG. 4

A comparison offering further difficulties is the following:

Diphenyl	99.6
" ether	75.7
Benzophenone	100.0

These results have been repeated and verified, though absolute values cannot be duplicated as a rule. The decrease from diphenyl to the ether must be due to a change in configuration of the molecule caused by the introduction of the oxygen atom. If this is the explanation, we are not able to describe the nature of the change as yet. The increase from the ether to the ketone is rather marked, but further data are required before any conclusions can be drawn. This increase is probably analogous to the increase in solubility in water of acetone over ether.

A comparison which at present seems to offer some difficulties in the way of satisfactory explanation is

Triphenyl methane (C_6H_5) ₃ CH	123.4
" carbinol (C_6H_5) ₃ COH	111.7

It would seem very difficult to explain the higher value for the hydrocarbon, unless we should go so far as to assume that by means of steric hindrance

¹ J. Am. Chem. Soc., 47, 2468 (1925).

the hydroxyl of the carbinol is prevented from exercising any effect. This would be the case if we had a configuration such as shown in Fig. 4. Any such explanation must of course be put forward with reserve, and requires additional evidence.

Some information concerning the effect of double bonds is available from Table IV. Below are tabulated the values for six pairs, the double-bonded compound being the second in each case.

Undecylic acid	50.8	Behenic acid	47.9
Undecylenic acid	70.0	Erucic acid	46.2
Hydrocinnamic acid	87.2	Hydrazo benzene	118.7
Cinnamic "	127.7	Azo benzene	104.5
Stearic acid	56.8	Dibenzyl	118.8
Oleic acid (Harkins)	89.62	Stilbene	94.7

In the first three cases the increase due to the double bond is considerable. In the last three there is a decrease. This would seem to fit in with the theory proposed a short time ago by T. M. Lowry¹ that double bonds are of two kinds. The first he calls the non-polar, and the second the semi-polar. The non-polar bond consists of two co-valences and the semi-polar of one co-valence and one electro-valence. At any rate we should feel quite safe in saying that there is a wide distinction between the double bonds of the first three and of the last three pairs. Just why any such bond should show what is apparently a decrease over the saturated compound is not clear. It is hoped that later evidence will throw light on the matter.

Spreading

The spreading of substances, particularly solids on liquids, as shown by the well-known case of camphor particles placed on water, has long been the subject of speculation. A complete and satisfactory explanation is however lacking. Various theories have been proposed, most of which have been associated with the effect of substances that spread on the surface tension of the liquid. It seems likely that this explanation is not sufficient for in certain cases of violent spreading the reduction of surface tension is very slight and other factors such as solubility and volatility affect the spreading. Trichloro tertiary butyl alcohol serves as a good example of some of these effects. When a small amount is first added to water the surface tension seems unaffected. After a few minutes the surface tension is gradually lowered until after about a half hour the decrease may amount to as much as 13%, depending on conditions. If the experiment is conducted in a small vessel which may be closed air tight, it will be found that as long as relatively small amounts are used and the vessel left open, violent motion will continue. If much larger amounts of solid are used, motion will cease as the water becomes saturated, or it will also stop if the cover is put on and the air becomes saturated (apparently) with the vapor of the substance. In the latter case slight motion is resumed

¹ Lowry: J. Chem. Soc., 123, 822 (1923); Bull., 39, 203 (1926).

if the cover is again removed, though the degree of motion is very much less than before. Consequently, it seems certain that solubility, and to a much less extent, volatility, are factors in spreading.

Table IV does not contain sufficient data to warrant any conclusions, since it shows only that in most cases of spreading the surface tension is lowered. Substances which show no spreading do not reduce the surface tension. The violence of spreading does not seem to be proportional to the surface tension lowering.

Effect on Orientation of Conditions during Crystallization

While a substance is crystallizing, heat and humidity have a large influence in determining the nature of the exterior face of the solid; in fact it is for this one reason, if for no other, that different samples of the same substance give different values. To insure reproducibility would require careful control of conditions during crystallization. It is rather surprising, in a way, that even in the solid phase some molecules are able to turn with such ease and to present an oriented arrangement. These facts are illustrated rather nicely by Table V which is practically self-explanatory, representing a series of experiments in which the humidity was varied considerably. The work of adhesion for stearic acid varies from 39.7 where crystallization took place in perfectly dry air at low pressure, to 131.0 when crystallization occurred in air saturated with steam at about 35°. Experiments G, H, J and K show that

TABLE V
Effect of Conditions during Crystallization on Orientation

	Stearic Acid	Capric Acid
A. Cooled in vacuum desiccator at 15-20 mm. over P_2O_5	W = 39.7 54.0	W = 58.4 58.4
B. Cryst, in Lab. air at 23° Ordinary humidity	65.2	52.2
C. Cryst. 2 ft. from escaping steam	80.2	
D. Cryst. 1 ft. from escaping steam	104.5	
E. Crsyt. in cloud of steam and read immediately	131.0	71.2
F. Crsyt. in cloud of steam, Value 2 min. Apparently steady.	111.2	71.2
G. Samples cooled in desiccator, then in contact with water, after 2½ hrs.	74.2	70.8
H. Samples cooled in desiccator, then in contact with water, after 24 hrs.	75.3 70.3	
J. Sample cooled in desiccator left in Lab. air at 23°—2½ hrs. " " 24 hrs.	67.7 88.0	
K. Sample cooled in desiccator and read at intervals after immersion in water		0 minutes 58.4 15 minutes 61.6 3 hours 61.0
L. Cryst. in contact with water 4/2/27 11/19/26-	70.3 65.2	

samples crystallized as in A, after immersion in water at ordinary room temperature for some time, even after comparatively short times (15 min. in K) show increased work of adhesion, i.e., increased orientation of polar groups toward the water. This process therefore seems to occur with comparative ease. Experiments B, C, D and E show the effect of increasing humidity while crystallization is taking place.

We are as yet at a loss to explain the great difference between experiments E and L for stearic acid where crystallization occurred in steam and on water.

Conclusions

1. A preliminary study has been made of two principal methods of measuring contact angle. These are

- (a) the Ablett cylinder
- (b) the plate method

The first of these is considered more or less uncertain at present, since it shows mysterious, unexplainable, and inconsistent results compared with the plate method.

2. About 70 organic substances have been studied for contact angle, effect on surface tension of water, spreading, and work of adhesion. The results, in all cases, appear to be in accord with other results on liquids and solids and with theories proposed by Harkins and Langmuir.

3. Some evidence on spreading is given. It is shown that some substances which spread violently do not affect the surface tension very greatly. Substances which do not spread do not lower the surface tension.

4. The effect of humidity during crystallization is very marked. Increased humidity while solidification takes place causes great increase in work of adhesion. Increase in number of polar groups exposed to water also occurs if the solid is immersed in water.

THE PHOTOCHEMICAL DECOMPOSITION OF HYDROGEN IODIDE; THE MODE OF OPTICAL DISSOCIATION¹

BY BERNARD LEWIS²

Introduction

Part I. Kinetic

The problem of determining by direct experiment the true mechanism of the photochemical decomposition of hydrogen-bromide or hydrogen-iodide studied by Warburg³ is of no little interest and importance since such knowledge would afford information concerning the conditions under which a molecule decomposes after it has become activated as a result of absorption of radiation.

It will be recalled that Warburg suggested the following steps in the decomposition after a thermodynamic consideration of the possible occurrence of secondary "dark" reactions:

where X denotes the halogen atom.⁴ This accounts exactly for the experimentally determined quantum efficiency of two molecules decomposed for each quantum of energy absorbed. Stern and Volmer⁵ have presented an entirely different point of view which does not violate the observed quantum efficiency. They argue that in this type of reaction a collision is necessary between the active molecule and some other molecule during the mean life of the active state before decomposition can take place and they conclude that the hypothesis that molecular dissociation or decomposition is the primary light process, cannot be entertained. Some of the bases of their arguments have since been found to be untenable. For instance, assuming the heat of dissociation of Cl_2 as 106,000 calories they pointed out the impossibility of a direct splitting of the chlorine molecule into atoms as a result of absorption of radiation since the energy available in the spectral region in which the combination of hydrogen-chloride occurs, namely about $\lambda = 4000\text{\AA}$, ($\text{Nh}\nu = 71,300$ calories) is considerably less than the heat of dissociation of chlorine. A collision therefore seemed necessary to meet the added energy requirement. This must now be ruled out since the heat of dissociation of Cl_2 as more recently determined kinetically⁶ and spectroscopically⁷ is 54,000 — 58,000 calories. Thus there is sufficient energy available in the quantum. That Cl_2 does dissociate in a single and elementary act by absorption of radiation in this region will be evident from spectroscopic considerations presented in Part II of this introduction.

It is true, however, that experiments on gas fluorescence⁸ and on the excitation of molecular spectra by electron impact⁹ show that at low pressure a

molecule may absorb many times its dissociation energy without dissociating. For example, iodine, whose heat of dissociation is 34,500 calories⁶ can absorb and emit as a resonance spectrum, an amount of energy five times the work of dissociation, when illuminated by the line $\lambda = 1849\text{\AA}$.¹⁰ Again a hydrogen molecule excited by electron collision can emit as molecular spectrum several times the amount of the dissociation energy. From the excitation of x-ray spectra, values of the excitation energy can be evaluated which may exceed the work of dissociation a thousand times without leading to dissociation by a primary process. The explanation of this effect seems to be found in the primary employment of the excitation energy in raising the electron system to a higher quantum state, while the oscillation and rotation energies are only altered by the coupling of their periods with those of the electron system.¹¹ Another plausible explanation, more applicable to complex molecules, is that, under certain conditions, there may be a finite interval between the absorption of energy and the decomposition of the molecule, since the former may not be distributed at once in the particular manner necessary for dissociation. During this interval a collision or some other disturbing factor may cause the emission of the energy as radiation.

Conceiving the primary light process as resulting in an energy-rich modification of the molecule, which, on the Bohr conception would be a molecule with an electron in an orbit farther removed from the nucleus, Stern and Volmer prefer to write

where $[\text{HX}]_b$ indicates the active state. In order to suit its condition to its surplus energy the active molecule requires a collision with another molecule before it can decompose,

the steps of which may be several and of the type proposed by Warburg in his thermodynamic treatment.¹² According to these authors this will occur provided the active molecule suffers a collision during its term of life, viz., ca. 10^{-7} sec. which has always been the case in the concentrations hitherto investigated. (Warburg worked at pressures of HI ranging from 80 m.m. to 350 m.m.). Otherwise the energy will be radiated or dissipated as kinetic energy. With inert gases or hydrogen present a small portion of the energy may be transferred to the foreign gas at each collision, the excited HI molecule taking up new and successive rotational quantum states, which, according to Stern and Volmer, seems possible with halogen-hydrides judging from their rather complicated infra-red spectrum. A sufficient number of successive collisions with a foreign gas may finally result in the deactivation of the $[\text{HX}]_b$ molecule. This would of course presuppose a relatively long life for the active state which is not inconceivable for rotational quantum jumps as the calculations of Tolman¹³ show. The decomposition of HBr and HI was studied by Warburg in the presence of N_2 and H_2 . Neither here nor when HI was mixed

with 0, 1 or $2\frac{1}{2}$ atmospheres of N_2 ¹⁴ was the decomposition affected in the least, the quantum efficiency still remaining two. This does not exclude the possibility of the reaction taking the course

since $[HI]_b$ evidently may keep its energy after a collision with certain molecules. It is a fact now coming to light that active molecules show varying susceptibilities to change on collision with different foreign gases.¹⁴

Bodenstein¹⁵ concluded that the photochemical decomposition of HI is unimolecular and Trautz and Scheifele¹⁶ reach the same conclusion for the early stages of the reaction. This does not signify that collisions are unnecessary since the decomposition may still be unimolecular with respect to the active molecules as presented in a mechanism above.¹²

From a kinetic point of view probably the most direct method which will enable one to determine whether the excited molecule may decompose without the stimulus of a collision, is to study the quantum efficiency at sufficiently low pressures of pure gas so that a molecule of HI, activated by absorbed radiation, is unable to make a collision with an ordinary HI molecule before its mean free life, viz., 10^{-7} sec.¹⁷ has terminated or before it decomposes of its own accord. In the former case if reversion takes place i.e. if a molecular encounter is a condition which must be fulfilled for decomposition, one would expect the quantum efficiency to be small. In the latter case if the molecule decomposes in a single act, the quantum efficiency should remain two as at high pressures. The results are markedly different and it should not be difficult to distinguish between these two alternatives. Accordingly, the present paper contains an account of these experiments in full.

Part II. Spectroscopic

Since the writer purposed studying this reaction, spectroscopic data¹⁸ of considerable importance have been published on which the results of these experiments have direct bearing.

Franck¹¹ pointed out that molecules which are bound together by van der Waals' forces such as the halogens can be separated into atoms by an adiabatic process and that illumination with radiation of the proper wave-length may cause dissociation into normal and excited atoms in a single act. The considerations due to Franck leading to this conclusion will be given in brief. Whether a photochemical dissociation is possible in an elementary act is dependent on the magnitude of the changes in oscillation and rotation energies which are coupled with changes in the electron system on absorption of light. Dissociation can take place when this change equals the energy of dissociation for the state considered. In the absorption spectrum a band convergence limit appears whenever the binding energy of the unexcited molecule in the lowest oscillation quantum state is changed by a suitable amount by transition of the electron system to a new quantum state due to absorption of light. Since the electron jump occurs so quickly that the heavy atoms maintain their relative position to each other during the transition period, potential energy is conveyed to the nucleus due to the electron jump. This

potential energy is dependent on the change in binding. With strong changes in binding, the potential energy is greater than the work of dissociation for the excited state and the molecule dissociates. By exchange of potential to kinetic energy the molecules break up with kinetic energy and instead of a band spectrum a continuous spectrum appears whose maximum is often displaced away from the convergence limit toward shorter wave-lengths. With iodine⁷ the change in binding is so great that the maximum absorption is found in the neighborhood of the convergence limit whereas with chlorine⁷ it is displaced considerably in the continuum toward shorter wave-lengths. It is concluded that the absorption of light of wave-length equal to or shorter than this limit ($\lambda = 4995\text{\AA}$ for I_2 ; $\lambda = 4785\text{\AA}$ for Cl_2) will lead to dissociation of non-polar molecules in an elementary act.

The earlier views of Franck have been amplified and clarified recently.¹⁹ F. Hund²⁰ has shown that the processes involved in the transition of an electron from the system of the anion to that of the cation are indicated from the principles of quantum mechanics. The process of decomposition in an elementary act by absorption of radiation can now be extended to polar molecules. Kondratjew²¹ has presented what seems to be conclusive experimental evidence that sodium-iodide may so decompose into a normal I atom and an excited Na atom.²² He finds that at 10^{-3} m.m. Hg the sodium D lines are emitted in a sharply defined beam whose dimensions are given by the boundary of the exciting cone of light. If a collision were necessary to disrupt the NaI molecule the excited molecule could have moved several centimeters (mean free path ca. 5 cms.) outside the zone before suffering a collision and the fluorescence would have been located far removed from the cone of exciting radiation. Furthermore, Kondratjew found that the fluorescence is proportional to the first power of the pressure²³ which seems unequivocally to signify that NaI decomposes in an elementary act by absorption of radiation. Terenin²⁴ showed that all wave-lengths below $\lambda = 2500\text{\AA}$ give rise to the emission of the sodium D lines in NaI vapor indicating that NaI should absorb continuously in this region, which Franck, Kuhn and Rollefson have shown to be the case.¹⁹

It would appear further from the work of Franck, Kuhn and Rollefson and Franck and Kuhn²⁵ that although HI, possessing infra-red rotation-oscillation absorption spectra and a small dipole electric moment, is considered polar in character, its atoms are not bound by the same type of forces as exist in the alkali-halides. The latter are characterized as "ion-linkages" where the forces exist between ions and the HI molecule as an "atom-linkage" where the forces exist between the nuclei, the criterion being the constituent parts into which the molecule decomposes. The view that the halogen-hydrides possess a different type of binding than the alkali-halides is strengthened not only by the criterion set up by these authors for their distinction but also by the work of Bell.²⁶ From a determination of the constants of the equation of the infra-red absorption bands of the halogen-hydrides, Bell was able to evaluate the variation with distance of the force acting on the hydrogen nucleus as it vibrates along the line joining the two nuclei. The results show that the

hydrogen nucleus is within the halogen electron shell and is buried to the same depth in all. If this is the case, then the union of a hydrogen atom with an iodine atom consists of a transfer of the hydrogen electron to complete the iodine shell and the penetration of the hydrogen nucleus within the iodine electron shell.²⁷ One would hardly expect the binding force to be ionic in character but rather as one between the nuclei. In fact it has been shown²⁸ that the lattice structure of HCl is atomic and not ionic. Indeed from these facts as well as both the character of the continuous absorption spectrum and its mode of decomposition one might consider HI as more nearly approximating to a non-polar than to a polar molecule despite its display of infra-red spectra and a small dipole electric moment.

Both Tingey and Gerke¹⁸ and Bonhoeffer and Steiner¹⁸ believe the continuous absorption of hydrogen-iodide to be sufficient evidence to eliminate Stern and Volmer's mechanism and to be consistent with Warburg's mechanism. However, direct experimental proof that a primary decomposition can occur without a collision is desirable, especially since the character of the absorption spectrum of HI is different from that of non-polar and strictly polar molecules such as NaI, no band convergence nor maxima in the continuum being observed.

Determination of the Experimental Pressure of HI to be employed in the present investigation and the probability of collision of an active molecule

Assuming in agreement with known data, that the mean life of a molecule in its electronic excited state is of the order 10^{-7} sec., one may calculate the gas pressure at which on the average a collision will not occur during this time interval. From the kinetic theory the number of collisions per second between an active HI molecule and any other HI molecule²⁹ is given by

$$Z = 2\sigma^2 n_1 \sqrt{2\pi kT} / m \quad (1)$$

where n_1 is the number of molecules of HI per c.c.

m is the mass of an HI molecule.

T " " absolute temperature.

σ " " sum of the radii of the participating molecules or the mean distance of approach of their centers.

k is the Boltzmann constant.

$$n_1 = p N / RT \quad 1333.3 \quad (2)$$

where p is the partial pressure of HI in m.m. Hg.

N is the no. of molecules per gram mol.

From this it follows that

$$Z = \sigma^2 p \cdot 5333.2 \sqrt{\frac{\pi N}{kTm}} \quad (3)$$

where $k = R/N$

The expression $T = 1/\bar{u} = l/Z$, where l is the mean free path and u the root mean square velocity, gives the mean time between collisions or the duration of a mean free path.

$$1/Z = T = 1/\sigma^2 pA \quad (4)$$

$$\text{where } A = 5333.2 \sqrt{\frac{\pi N}{kTM}}$$

$$A = 5333.2 \sqrt{\frac{3.1416 \times 6.06 \times 10^{23}}{1.37 \times 10^{16} \times 300 \times 128}} = 3.21 \times 10^{21}$$

$$T = \frac{1}{\sigma^2 \times 10^{-16} p \times 3.21 \times 10^{21}} = \frac{31.2 \times 10^{-7}}{\sigma^2 p} \text{ sec.} \quad (5)$$

As first approximation we will allow $T = \tau = 10^{-7}$ sec. the mean life of the active state.

$$\text{then } p = 31.2/\sigma^2 \quad (6)$$

where σ is in angstrom units.

The value 2\AA for the diameter of the HI molecule given by W. C. McLewis³⁰ appears to be too small. From considerations above, namely that the hydrogen nucleus is buried within the iodine shell, the diameter of the normal HI molecule should be comparable with that of an I^- ion which, having the stable configuration of Xe should approximate the diameter of the latter. A comparison of the diameters may be made by calculating the diameter of HI from van der Waals' b . Unfortunately only the critical data for HCl and HBr are available, but by plotting b calculated from the critical data in the Landolt-Börnstein tables, against atomic number we arrive at a value $b = 2162 \times 10^{-6}$ for HI, whence $\sigma = 3.37\text{\AA}$. This compares well with 3.42\AA for Xe. In a similar way the values for HBr and Kr are 3.27\AA and 3.14\AA respectively. Since we are concerned with a collision between an excited and a normal molecule of HI some knowledge of the excited state is desirable. C'ario³¹ found in the case of Hg, that the diameter increased from 2.8\AA for the normal state to 9.1\AA for the excited state. Assuming in the extreme that the diameter of the excited HI molecule increased to 10\AA and substituting in (6) we obtain as a lower pressure limit

$$p = \frac{31.2}{(5 + 1.69)^2} = 0.693 \text{ m.m. Hg.}$$

In order to be well within the critical pressure it was decided to work with pressures of HI of about 0.1 m.m. Hg. At pressures lower than this it becomes very difficult to measure the absorbed radiation.

Since T is merely the time between collisions it is not strictly true that a collision will never occur within 10^{-7} sec. after absorption of radiation. One has to calculate the probability that a molecule will collide while still in the excited state. A method for this calculation has been worked out by L. A. Turner³² and is applied to the present case.

If τ is the average life of the excited state, then assuming random distribution of lives of excited molecules,

$e^{-t/\tau}$ is the chance that a molecule will remain excited in time t .

If T is the average time between successive collisions of an excited HI molecule and ordinary HI molecules,

$e^{-t/T}$ is the chance that a molecule will not collide in time t

$e^{-t+dt/T}$ is the chance that a molecule will not collide in time $t + dt$

The probability that the molecule will collide in the time between t and $t + dt$ is the difference between the last two probabilities. Expanding and keeping only the term with dt to the first power, gives:

$$e^{-t/T} (e^{-dt/T} - 1) = e^{-t/T} dt/T$$

The probability that the molecule will collide in the time between t and $t + dt$ while still in the excited state is the product of the probabilities for collision and duration of the excited state.

$$e^{-t/T} e^{-t/\tau} dt/T = e^{-(T+\tau)t/T\tau} dt/T$$

The probability that a molecule will collide while in the excited state for all values of t is

$$P = \int_0^{\infty} e^{-\frac{(T+\tau)t}{T\tau}} dt/T = -\tau/(T+\tau) \left[e^{-(T+\tau)t/T\tau} \right]_0^{\infty} = \tau/(T+\tau)$$

Thus the probability of a collision while the excited state exists is the ratio of the life of excited state and the sum of the time between collisions and the life of the excited state. We may now determine what percentage of the active molecules collide while still excited. Employing equation (5) and the experimental pressure of 0.1 mm. Hg. of HI,

$$T = \frac{31.2 \times 10^{-7}}{(6.69)^2 \times 0.1} \quad ; \quad T = 6.93 \times 10^{-7} \text{ sec.}$$

$$P = \frac{10^{-7}}{(6.93 + 1) 10^{-7}} = 12.6\%$$

Thus choosing the most unfavorable conditions only 12.6% of the excited molecules collide while still excited while assuming no change in the diameter this reduces to only 3.5%.

Experimental

The method consists in illuminating HI gas at about 0.1 m.m. Hg pressure, measuring the radiation absorbed and the extent of decomposition by freezing out the I_2 and HI and determining the residual H_2 . Only the early stage of decomposition was studied to avoid secondary absorption by the iodine liberated.

a. Apparatus. The experimental arrangement is shown in Fig. 1. L , the source of radiation, consists of a condensed zinc spark, equipped with a micrometer for fine adjustment, connected in parallel with a large plate glass condenser immersed in transformer oil. This in turn was in parallel with the secondary of a large transformer coil whose primary took 65 amps, at 110v. A. C. The latter stepped up to about 40,000v. The electrodes were vertical and were cooled by a blast of nitrogen to prevent oxidation of the Zn and consequent absorption of the ultra-violet bands by the fog of ZnO. In this way a steady spark was maintained.

The optical system O, consisting of a large quartz prism and suitable lenses, served to separate the two strong Zn ultra-violet bands at $\lambda = 2080\text{\AA}$ and $\lambda = 2530\text{\AA}$ ³³ which were also employed by Warburg. The parallel beam was arranged to just illuminate the entire rear window of the quartz cell. By means of an opening in a zinc sulphide fluorescent screen S, on which the lines were sharply and brilliantly defined, either of the bands could be utilized at will.

FIG

The clear quartz reaction cell, C, 30.1 cms. long and 2.7 cm. in diameter was provided with optically plane and parallel ends and two quartz-to-pyrex graded joints, connected on the one side to a liquid-air trap, F, and a magnetic hammer device, A, (shown enlarged) for fracturing a small capillary, G, filled with HI, and on the other to a bifilar quartz fibre manometer, M, (shown enlarged) for measuring small pressures of H_2 , a carefully calibrated McLeod gauge and mercury vapor high vacuum pumps. A cadmium-liquid-air trap was used to protect the apparatus, mercury pumps and McLeod. The two quartz fibres in the manometer were sealed together at one end to a small glass indicator³⁴ to prevent elliptical motion as suggested by Coolidge.³⁵ The radiation was measured with a sensitive galvanometer protected from stray magnetic fields, and a Moll thermopile, T, equipped with a fluorite window and receiving funnel 2.60 cms. in diameter.

b. Calibration of Moll Thermopile. The thermopile was calibrated against a standard radiation lamp furnished by the Bureau of Standards. Accompanying directions kindly provided by Dr. Coblenz were rigidly adhered to. The table accompanying the lamp is reproduced in Table I.

TABLE I

Amps	Volts	Radiation intensity
		Watt/ $\overline{\text{m.m.}}^2$
		Distance two meters from lamp
0.250	79.9	42.6×10^{-8} watts
0.300	94.8	62.7×10^{-8} "
0.350	109.8	86.7×10^{-8} "
0.400	125.0	114.4×10^{-8} "

Table II shows the calibration results, the second column giving the total radiation received by the thermopile (the area of the funnel being $530.7 \overline{\text{m.m.}}^2$). Experiments indicated that all the radiation entering the funnel reached the thermo-couple. The fourth column allows for absorption of a fluorite window indicated in the directions.

TABLE II

Amps	Total Radiation Watt/sec.	Deflection of Galvo. in m.m.	Flux/m.m. de- flection allowing 91.6% fluorite transmission; watt /sec./m.m.	Average value of Flux; ergs/ sec./m.m.
0.250	22.61×10^{-5}	300.0	6.91×10^{-7}	
0.300	33.27×10^{-5}	443.1	6.88×10^{-7}	6.87
0.350	46.01×10^{-5}	618.3	6.82×10^{-7}	

Calculation of number of Quanta received by the thermopile per second per m. m. deflection.

I. For $\lambda = 2080\text{A.}$

$E = h\nu = hc/\lambda$ where h is Planck's constant
 c is velocity of light in cm/sec.
 λ is wave-length in cm.

$$E = \frac{3 \times 10^{10} \times 6.55 \times 10^{-27}}{2080 \times 10^{-8}} = 9.45 \times 10^{-12} \text{ erg (value of one quantum)}$$

$$\frac{6.87}{9.48 \times 10^{-12}} = 7.27 \times 10^{11} \text{ quanta/sec./m.m.}$$

II. For $\lambda = 2530\text{A.}$

$$E = \frac{3 \times 10^{10} \times 6.55 \times 10^{-27}}{2530 \times 10^{-8}} = 7.77 \times 10^{-12} \text{ erg.}$$

$$\frac{6.87}{7.77 \times 10^{-12}} = 8.84 \times 10^{11} \text{ quanta/sec./m.m.}$$

c. *Calibration of the Quartz-fibre Manometer.* Since hydrogen was to be measured, the manometer was calibrated at low pressures against the McLeod using pure dry hydrogen, the time of decay of the amplitude of vibration of the indicator between the glass points p_3 and p_2 being noted for different pressures. Care was exercised to exclude all Hg vapor. The image of p_3 and p_2 was observed with a traveling micro-telescope with cross-hair. Care must be taken to preserve the distance between the position of the swinging fibres when at rest and the points p_3 and p_2 . By plotting the pressure of H_2 against the reciprocal of the decay time practically a straight line was obtained at low pressures. All conditions were maintained the same as existed in the actual experiments.

d. *Preparation of capillaries containing HI gas.* The volume of the reaction system which included the quartz cell, manometer, liquid-air trap and magnetic hammer, was 232.5 c.c. A series of small capillaries about 1 m.m. in diameter and 4 to 6 cms. long were constricted at the proper length such that their volumes were approximately 1/7600 of the reaction system. Such a capillary filled with HI at standard conditions would when fractured give a pressure of about 0.1 m.m. HI. The exact pressure could be determined by calibration of the capillary. HI was drawn from a specially prepared strong solution for the use of which I wish to thank Professor S. C. Lind. The HI gas was frozen out in a liquid air trap, water vapour being removed by a $CaCl_2 - P_2O_5$ tube and most of the I_2 by a freezing bath. All of the I_2 was removed by 3 or 4 low temperature distillations. Further purification was effected just before filling the capillaries by 3 low temperature distillations under high vacuum. The capillaries were thoroughly evacuated and HI allowed to expand into them. The pressure was relieved to that of the atmosphere by gently heating the end of a small piece of constricted glass and then quickly sealing. Each capillary was removed in turn at the fine restrictions with a minute jet flame. In this way a very pure HI gas was obtained.

e. *Experimental procedure.* The experimental procedure was as follows: After the reaction system was thoroughly and completely evacuated, the tip of a capillary was broken and the HI frozen out in the liquid air trap. The pumps were again connected to remove the slightest trace of H_2 that may have been present in sealing off the capillary. The amplitude decay time for high vacuum and the galvanometer reading for incident radiation at a given setting of the electrodes were taken before and after each run and were found to check well. The HI was allowed to expand into the reaction system and exposed to the desired ultraviolet band, galvanometer readings being taken every 10 seconds, and after a given time of irradiation it was frozen out together with the I_2 formed. The decay time for the residual H_2 was noted and the pressure read from the calibration chart. From this was calculated the number of molecules of HI decomposed. The energy absorbed was the difference between the galvanometer readings for incident radiation and the average reading while the decomposition was in progress. The various parts

of the apparatus and light source were carefully shielded and the reaction system covered with black paper. The experiments were conducted in a dark room free from draughts, the temperature being about 27°C .

Results

Before presenting the results certain corrections must be made. The absorption of radiation of one quartz plate must be determined. This was found to amount to 15.2% for the line $\lambda = 2080\text{\AA}$ and 8.85% for the line $\lambda = 2530\text{\AA}$. Therefore the total absorption of the lines must be multiplied by the factors 1.18 and 1.097 respectively. A correction for difference in areas between that of the cell window and the thermopile necessitates a further multiplication of the absorption measurements by 1.08 (The area of the window was 573 m.m.² as against 530.7 for the thermopile). Table III presents the results of a series of runs carried out with each line.

A sample calculation from data in experiment 2 will illustrate the method.

Absorption in m.m.	7.83
Time of exposure in seconds	516 $\frac{3}{5}$
No. of quanta absorbed/sec./m.m. ($\lambda = 2080$)	7.27×10^{11}

Volume of cell	232.5 c.c.

Total molecules of HI decomposed =

$$2 \left(\frac{0.0007}{760} \times \frac{273}{300.2} \times \frac{232.5}{22400} \times 6.06 \times 10^{23} \right) = 10.5 \times 10^{15}$$

$$\frac{10.5 \times 10^{15}}{3.76 \times 10^{15}} = 2.79 \text{ molecules}/h\nu$$

The difficulty of measuring the absorption of radiation increases greatly at low pressures. It is therefore desirable to determine whether the measurements are of the correct order of magnitude. This can be done by calculating the coefficient of absorption from the above data using Beer's law and comparing it with the value found by Warburg at higher pressures. The average value for μ , the absorption coefficient, was found to be 0.0427 and 0.0251 for $\lambda = 2080\text{\AA}$ and $\lambda = 2530\text{\AA}$ respectively whereas Warburg found 0.0270 and 0.0139. Warburg's values varied for different set-ups of the apparatus. However the coefficients are of the right order of magnitude and the agreement satisfactory.

Discussion of Results

It is observed that the number of molecules decomposed for each quantum absorbed is about two as Warburg also found at higher pressures (80 m.m. to 350 m.m.). This indicates that an activated hydrogen-iodide molecule does not require a collision to suit its condition for decomposition.

A question of interest is the fate of the surplus energy namely the difference between the absorbed 137,000 calories ($\lambda = 2080\text{\AA}$) and 68,000 calories the heat of decomposition of HI from thermochemical data, or 69,000 calories. The first electron level for the hydrogen atom is 10.2 volts or 236,000 calories. Thus excitation of the hydrogen atom is out of the question. From theoretical considerations and spectroscopic data Franck and Kuhn²⁵ have pointed out that HI like AgI is a non-ion linkage, the first stage in its dissociation as shown by the long wave-length limit of its continuous absorption spectrum, taking place not into two normal atoms but into a normal and excited atom. No maxima were observed in the continuum down to $\lambda = 2000\text{\AA}$ and thus no transition occurs in the mode of decomposition and therefore in the type of binding. From the long wave-length limit of the continuous absorption band, about $\lambda = 3200\text{\AA}$, we obtain 89,000 calories. This value, less the heat of dissociation of HI gives 21,000 calories which is just the energy required to excite the iodine atom from the stable $2P_2$ state to the metastable $2P_1$ state. It is noteworthy that absorption does not begin at a point where the energy is just equal to the heat of dissociation of HI; therefore the latter cannot dissociate into two normal atoms. Similarly in the case of I_2 the energy corresponding to the band convergence limit where the molecule begins to dissociate, exceeds the dissociation energy by about 0.9v. or 21,000 calories, which represents dissociation into a normal and an excited atom in the $2P_1$ state. There remains 48,000 calories to be accounted for. An attempt was made to observe a visible fluorescence in the iodine liberated but without success. That the iodine atom is not excited further than that represented by the $2P_1$ state is evident from the present results for otherwise a quantum efficiency of 4 would be expected particularly at low pressures where complicating secondary effects prevalent at higher pressures, are absent. By a collision of the second kind the endothermic reaction (about -28,000 calories)

could proceed and then

The quantum efficiency at low pressures being slightly in excess of 2 may be explained on the basis of the occasional occurrence of the above process with an iodine atom in the $2P_1$ state possessing an exceptional velocity dictated by Maxwellian distribution. It must be concluded that the 48,000 calories are dissipated as kinetic energy.³⁶ In the division of this energy between the hydrogen and iodine atoms, nearly all of it is assumed by the hydrogen on the principle of conservation of momentum. This accounts for the fact that

every impact between H and HI (a reaction which is ordinarily exothermic but which nevertheless possesses a critical energy increment for reaction by collision) results in the decomposition of the latter.

It is of interest to note that since collisions are unnecessary for the dissociation of HI, the time between absorption of radiation and decomposition may be less than 2×10^{-10} sec., the average time between collisions as calculated from Warburg's highest pressure.

From the spectroscopic side it may be concluded that the same interpretation of the continuous spectrum exhibited by hydrogen-iodide may be adopted as was proposed for non-polar molecules; that gaseous hydrogen-iodide dissociates in a single and elementary act after absorption of radiation into a normal hydrogen atom and an excited iodine atom.

Summary

The photochemical dissociation of hydrogen-iodide was studied at low gas pressure where the collision frequency is comparable with the mean life of the excited state. Quantum efficiency of the process was found to be about 2 which agrees with Warburg's value for high gas pressures. This indicates that hydrogen-iodide dissociates in an elementary act as a result of absorption of radiation without the necessity of a collision. From the continuous absorption spectrum it is shown that dissociation takes place into a normal hydrogen atom and an excited iodine atom in the metastable $2P_1$ state, the excess energy if any, being dissipated as kinetic energy. It is pointed out that the time between absorption and dissociation is shorter than 2×10^{-10} sec.

It is a pleasure to acknowledge the kind interest shown by Professor S. C. Lind during the progress of this work.

²⁷ It may be significant that the electron affinity of I^- calculated from Born's method of grating energy of crystals as 81,000 calories (Foote and Mohler: "Origin of Spectra") is quite close to that evaluated from the long wave-length limit of the continuous absorption of HI. It is therefore possible that HI will only dissociate when sufficient energy has been absorbed to cause I^- to part with its extra electron. In the final adjustment, the energy over and above the thermochemical value goes to excite the iodine atom as will appear later.

³⁵ *J. Am. Chem. Soc.*, **45**, 1637 (1923).

³⁶ This conclusion is in agreement with the theory of Franck. A private communication from T. R. Hogness working in Göttingen, Germany, states that when gaseous NaI molecules are excited by a frequency greater than that necessary for dissociation, the excess energy is dissipated in the form of kinetic energy of the dissociating atoms. The greater the excess energy the greater the kinetic energy of the dissociating atoms, hence the greater the Doppler effect of the D lines emitted.

THE VOLUME CHANGES ATTENDANT ON MIXING PAIRS OF LIQUIDS

BY JOHN BUTTERY PEEL, WALTER MATTHEW MADGIN, AND
HENRY VINCENT AIRD BRISCOE

It has been held¹ that the changes in volume and temperature occurring when liquids are mixed are closely related. It has been shown, however, (1) that a decrease in volume may accompany a fall in temperature, and that even when a decrease in volume is associated with a fall in temperature the maxima of these effects may occur with mixtures of different compositions² and (2) the diminution in volume in a given case (chloroform: ether) was much less than the heat of mixing³ would suggest. From a consideration of several cases, Young⁴ concluded that "the thermal and volume effects do not, in many cases, run *pari passu*, though where a rise of temperature accompanies an increase in volume, or vice versa, both effects are relatively small."

Though two investigations⁵ have dealt with the relationship between changes in volume and in other physical properties, none has yet dealt systematically with the possible connection between volume change and thermal effect in binary mixtures. It was, indeed, a prior condition of such an investigation that a broad survey should be made of the sign and magnitude of the thermal effects in a large number of cases, and this has but recently been done.⁶

It has now been possible to select a number of pairs of liquids covering a wide range of thermal effects, and for these to determine in a systematic fashion the variation of change of volume on mixing. The results of this work are given here.

Experimental

The volume changes for each liquid pair were found by determining the densities of the pure liquids and several mixtures of known composition, using 30 cc. silica Sprengel pyknometers having a bulb on the short limb and ground silica caps on both limbs to prevent evaporation. Irregular results obtained at first with both glass and silica pyknometers were traced to changes in the composition of liquid mixtures by fractional evaporation during filling by suction. Possibly such evaporation effects account for the very irregular results previously obtained for some liquid pairs (e.g., Bussy and Buignet for ethyl alcohol: carbon disulphide). Therefore, in the determinations recorded, the pyknometer was filled by forcing the liquid into it from a closed vessel in a

manner similar to that described by Briscoe, Robinson and Stephenson, the vessel B being replaced by a large test-tube fitted with a rubber stopper carrying the tubes P and H. A mercury-filled Hempel burette was used to apply air-pressure through H.

FIG. 1

In preparing the liquid mixtures (approximately 50 cc. for each experiment) the proper quantity of the more volatile liquid was weighed into a well-stoppered concial flask, and a measured volume of the second liquid was run in while the flask was kept cooled in running water. Thereafter the flask

¹ J. Chem. Soc., 129, 731 (1926) Fig. 3.

was immediately closed, and reweighed, the weighings being made against a tare and with all usual precautions. From the weight-composition of the mixture thus determined, the volume-composition was calculated, using the ascertained densities of the pure liquids.

FIG 2

The pyknometer, after filling, was brought exactly to $25^{\circ} \pm .01$ in a thermostat, the level of the liquid was adjusted in the usual way, the caps were fitted, and then the pyknometer was transferred to the balance case and weighed accurately against its tare. *Results.* The results are shown graphically in Figs. 1 and 2, where the volume changes, (positive above and negative below the OX axis) in cc. per 100 cc. of total constituent liquids, derived in an obvious way from the experimental data, are plotted as ordinates against the mixture-compositions as abscissae. The figures differ in that the composition

is expressed in Fig. 1 as volume percentage and in Fig. 2 as gram-molecular percentage. It is noticeable, and may be significant, that the curves in Fig. 1 tend to be more symmetrical than those in Fig. 2.

*In columns IV and V of the table, the positive sign (+) indicates an increase in volume or rise in temperature, and the negative sign (—) the reverse.

Table I affords a key to Figs. 1 and 2, giving the numbers (Col. I), corresponding with the 28 pairs of liquids (Col. II), being used to indicate their volume-curves in the Figures; the Table also shows for each liquid-pair the percentage volume-change (Col. IV) and the temperature change at 20° (Col. V) for the 50 per cent volume mixture. Certain prior results in isolated cases are indicated by the references in Col. III. Sometimes the earlier results differ from those now reported. Brown in the case of ethyl alcohol: chloroform reported a contraction for all compositions, but his curve, being based on three determinations only, happened not to show the small expansion which occurs with high proportions of chloroform. Holmes (*loc. cit.* p. 2162) concludes that methyl iodide and chloroform give "a small but appreciable expansion" on mixing and this is in agreement with curve 10 now reported. Aniline: carbon tetrachloride (24) give a contraction with a fall in temperature on mixing and Hartung¹ has found that these two liquids react slowly to form a compound. Curve 15 consists of two almost straight lines and this is in agreement with what Bramley² has found for the same mixture.

A careful scrutiny of Columns IV and V brings out with great clarity the chief result of this investigation: the volume and temperature changes evidently bear no relation to each other. A glance at cases 22 and 18 shows at once that there is no tendency even to a constancy of ratio between volume change and thermal effect.

This conclusion is supported by another consideration. In Table II are given for 20 cc. of 50% vol. mixture of selected liquid pairs, the heat of mixing (Col. IV) and the external work (also in calories) attributable to the observed volume change (Col. VI): these are derived in a manner which is evident from the columns of the Table. Here again it is evident that, in every case, the external work done by or on the mixture, accounts for but an insignificant fraction of the energy change involved. It is true that the method used in calculating Column IV (following precisely that of Kremann³, is likely to give a result in some cases in error by several tens per cent, but this is not of much moment when the difference between Columns IV and VI is many hundreds per cent.

Thus the results here presented afford evidence that practically the whole of the observed thermal effect of mixing liquids must be attributed to *internal* work done thereby. It is commonly believed that relatively great internal pressures exist in liquids and vary widely from one liquid to another: and it is conceivable that the observed thermal effect may be strictly equivalent to the work done in the volume change with or against these pressures. This view could be verified experimentally by determining the compressibility of mixtures formed with increase of volume, but the existence of cases such as Nos. 10, 12, 19, 20, 24, 26, where an increase in volume accompanies a rise of

temperature on mixing, and vice versa, renders it almost certain that this hypothesis is inadequate, and that a substantial part of the thermal effect, at least in many cases, is due to chemical changes on admixture.

In brief, the study of volume changes leads, as does that of temperature changes, to the conclusion that the observed effects are not properties of liquids in general but specific properties of chemical reagents. This idea is supported by a consideration of cases 19, 20 and 28, where it is evident that both thermal and volume changes vary regularly with progression up an homologous series.

It is perhaps significant, in this connection, that while gases at low concentrations are amenable to the gas laws, they exhibit in high concentrations highly specific deviations from these general laws. At the much higher concentrations existing in liquids, it would appear that the specific properties of the molecules are of primary importance.

This view receives some support from a study of the curves. It is evident that a number of these, e.g. Nos. 19, 20, 22, 23, 25, 26, 27, 28, are sinuous. Such sinuous curves have been obtained by several workers for several properties of liquid mixtures, (see, e.g., viscosity of phenol-pyridine mixtures,¹ vapour pressure of pyridine and water,² density of *n*-amyl alcohol and acetone, admixed with chloroform³), and Bramley has advanced the explanation that they are due to chemical changes in the liquids concerned.

As a further check, the thermal effects of adding to the 50% volume mixture further quantities of each of the constituent liquids have been examined: the results are given in Table III, as the temperature change in degrees produced on making the mixtures indicated at the top of the column.

TABLE III

Constituent Liquids		Temperature Change on Mixing:		
A	B	5A + 5B	(5A + 5B) + 5A	(5A + 5B) + 5B
Ethyl alcohol	: chloroform	+3.7	+2.6	-1.3
—do—	: carbon tetrachloride	-0.4	+0.7	-0.8
Ether	: chloroform	+1.4	+3.3	+2.1
—do—	: carbon tetrachloride	+2.8	+0.7	+0.6

In the first two cases, where the density composition curves are sinuous, the thermal effects of adding the constituent liquids to the mixtures are opposite in sign: in the last two cases these effects are similar. Thus it seems at least probable that, with an alcohol-chloroform mixture, addition of alcohol

A CONCEPTION OF POLARITY DERIVED FROM PHYSICAL MEASUREMENTS AND ITS RELATIONS TO THE ELECTRONIC CONFIGURATION OF AROMATIC ORGANIC COMPOUNDS

BY J. F. T. BERLINER

Introduction and Discussion

In a recent series of studies on the vapor pressures of a number of highly purified organic compounds several relations were observed that appear to merit further consideration. The compounds studied were the isomeric nitroanilines, mononitrotoluenes, toluidines and naphthols. In this discussion the latter group will be omitted.

Many determinations, direct and indirect, have been made of the heats of vaporization and to the present time but two generalizations have been evolved that can be related to chemical phenomena. The first is, that in general the latent heat per gram is less for substances of higher molecular weight, and the second that a relation exists between the entropy and the latent heat of vaporization that involves a consideration of the association of molecules.

As the kinetic energy associated with each molecule at the same temperature is the same, it follows that, as there are less molecules in one gram of substance of high molecular weight, there is also less total kinetic energy. The latent heat is, therefore, also less. The latent heats of vaporization are not simply inversely proportional to the molecular weight; several factors are involved, the principal ones being the mean square velocity of the molecules escaping from the surface of the liquid and the amount of heat necessary to overcome the intramolecular attraction. The velocity may be calculated from a consideration of the assumption that the ratio of the density of the vapor to the density of the liquid is the ratio of the molecules with sufficient speed to escape from the surface of the liquid to the number with insufficient speed. This assumption is justified in that many physical facts may be explained through it and it does not seem to be opposed to any of our present conceptions of vaporization, or its colligative properties. This idea is also applicable to solutions: Thus the lowering of the vapor pressure of a solvent, by the introduction of a non-volatile solute, is explained by considering that the number of molecules with sufficient speed to escape is thereby reduced relatively to the number with insufficient speed. On account of their electrical

nature, ions have to overcome a greater cohesive force in order to escape and consequently need a much greater kinetic energy than molecules. They are, therefore, largely non-volatile. In a similar way the forces of attraction between water molecules and other non-volatile molecules is probably greater than that between the water molecules themselves.

Recently MacLeod⁵ has published a comprehensive treatise on this phase of the subject and has pointed to a possible analogy between the mechanism of evaporation based on differential surface velocities of molecules and osmotic pressure phenomena. (See p. 542).

The nitroanilines and the nitrotoluenes have however almost the identical molecular weights, 138.06 and 137.06, respectively. From this consideration the same heat of vaporization for each compound might be expected. However, it was observed^{1,2} that the heats of vaporization of the isomers of the nitroanilines differ widely, and those of the nitrotoluenes, besides being very much lower than the heats of vaporization of the nitroanilines, also differ from each other to a small extent. As was indicated in the papers referred to above the nitroanilines appear to form highly associated molecules, while the nitrotoluenes are practically non-polar substances. When the heat of vaporization of an associated substance is arrived at through vapor pressure determinations, a factor is involved that may be called the heat of "deassociation," that is, the amount of heat energy necessary to decompose an associated molecule into normal non-associated molecules. This heat may be quite high and in the case of para nitroaniline is about 6600 calories (value arrived at from consideration of observed and calculated theoretical heat of vaporization) per mole. Therefore the abnormally high heats of vaporization of the nitroanilines may be readily explained and it is evident that one of the fundamental properties that must be taken into cognizance, in arriving at any conclusions from the experimental and derived data, is that of polarity or association. The heats of vaporization, while in themselves important, are dependent on the degree of molecular association and can not be correctly interpreted unless the extent of the latter condition is known.

The relations between the entropy of a liquid and its latent heat of vaporization were soon recognized; though at first the function now denoted as entropy was not recognized. In 1884 Trouton⁶ announced the rule that is now known by his name—that the quotient from the heat of vaporization per mole divided by the absolute boiling point, is approximately the same for all substances. This law has, in fact, been until fairly recently assumed to be at least approximately correct. The value of the quotient is about 20 to 22. The rule as it would now be stated is, that the entropy increase per mole is the same for liquids at their boiling point. It may be said that the validity of this rule would follow from the work of Guldberg⁷ who pointed out that the boiling point on the absolute scale is nearly always about two thirds the abso-

⁵ MacLeod: *Trans. Faraday Soc.*, **20**, 525-543 (1925).

⁶ Trouton: *Phil. Mag.*, (5) **18**, 54 (1884).

⁷ Guldberg, *Z. physik. Chem.*, **5**, 374 (1890).

lute critical temperature. A more rigid examination of Trouton's rule, shows, however, that the ratio is by no means constant, but increases regularly with the temperature, as was pointed out by Nernst⁸ and also by Bingham.⁹ Trouton's rule holds very well for non-polar liquids boiling in the neighborhood of 100° to 300°C. It has been derived theoretically from the theorem of corresponding states by Iterson;¹⁰ however, according to Bingham, it must hold more closely than this theorem.

For polar or associated liquids, such as water or alcohol, the Trouton ratio is larger. This is explained, as was previously indicated, by assuming that when a liquid is associated, and its vapor not associated, a certain amount of heat is required to dissociate the molecules of the liquid, hence the normal heat of vaporization is increased. The effect on the boiling point is doubtless not very large, so that when abnormally high values of the ratio are obtained the evidence of dissociation seems very satisfactory. The quotient from the heat of vaporization divided by the absolute boiling point represents the increase in entropy of the substance during vaporization. A rule essentially the same as Trouton's has been given by LeChatelier and Forcerand¹¹ wherein the entropy constant of certain solid compounds at a pressure of one atmosphere is approximately 33 calories per degree. Various modifications have been suggested for Trouton's rule. Two of these have been proposed by Nernst.¹² It is difficult to determine from what Nernst says, whether they have any other than an empirical foundation. They seem chiefly intended to take into account the low-boiling gases. Another formula has been proposed by Bingham¹³ which is also empirical and has been constructed without much reference to liquid boiling at very high or very low temperatures. More recently Forcerand¹⁴ has published a formula, also empirical, but which has attempted to include liquids with very high, as well as those with very low boiling points. The course of this equation at high temperatures was determined by using data for the boiling points of silver and copper. However, Forcerand's formula is not considered very significant.

The most important generalization has been given by Hildebrand,¹⁵ derived from the Clapeyron Clausius equation of state. The Clapeyron-Clausius equation may be put in the form

$$\frac{d \log p}{d \log T} = \frac{L}{RT}$$

Now L/T is the entropy, so that if $\log p$ be plotted against $\log T$, the tangent to the curve at any point is equal to the entropy divided by R , the gas constant. By plotting a number of curves, it was found that the points, where

¹⁵Hildebrand: J. Am. Chem. Soc., 37, 970 (1915); 40, 45 (1918)

their tangents had the same slope, were on a straight line which could be represented by $\log p = \log T - \text{constant}$. If the vapor obeys the gas laws then $p = cRT$ where c denotes the concentration. This may be converted into the logarithmic equation, $p = \log T - \log Rc$; therefore $\log Rc$ is the constant of the above equation. Along such a line as represented by this equation, the concentration must be constant, Hildebrand therefore states that: "The entropy of vaporization for normal liquids is the same when evaporated to the same concentration, i.e., when the final mean distance between the molecules of vapor is the same." It must be emphasized that Trouton's rule makes a comparison at constant pressure (one atmosphere) and not at constant concentration, and under constant pressure conditions the entropies are not the same. Any concentration may be chosen. Hildebrand arbitrarily chose the concentration of 0.00507 moles of vapor per liter, this concentration having the "desirability of avoiding any extrapolation" of his measured data. The value for the constant is approximately 13.7 calories per degree.

Applying Trouton's Rule, the increase of entropy constant varies greatly with substances of widely different boiling points; as, for instance, nitrogen and bromonaphthalene give values of 11.0 and 14.1 calories per degree, respectively, while with Hildebrand's expression the values for these two substances are the same—13.8 calories per degree. Hildebrand found that associated substances gave abnormal values, for instance, ammonia, water and ethyl alcohol gave 16.2, 16.0 and 16.7 calories per degree, respectively. He also found a small though significant difference for the metals which were on the average about 0.6 calories per degree lower than the normal liquids. It is suggested that this deviation is due to a difference in molecular complexity. When a molecule escapes from the liquid to the vapor it is relieved of a very high internal pressure which exists in the liquid, and may, conceivably, expand with an absorption of energy. The amount of energy so absorbed would be expected to be greater in the case of molecules containing many atoms than with those containing but a few.

The expression for the entropy of vaporization may therefore be written $(L - e)/RT$, where "e" denotes the energy absorbed within the molecules on expansion from the high pressures existing within the liquid to the low pressures existing in the vapor. The quantity of "e" is doubtless small compared to "L", that is most of the energy is required to overcome the attraction between the molecules, and but little in the expansion of the molecule itself. It may be stated that, in all probability, in so far as it concerns the overcoming of the attraction between molecules, the entropy of vaporization at the same concentration is the same for all normal liquids. If a liquid is associated, a third, and much larger quantity of energy is involved in the dissociation of the complex molecules into simpler ones. In such cases the total entropy of vaporization is distinctly greater than the normal values for a given concentration. Hildebrand considers that the low values of metals and also of gases boiling in the region of absolute zero are due to effects of the abnormally rapid changes of the specific heats.

The entropies of vaporization of the nitroanilines, toluidines and nitrotoluenes at temperatures at which the concentration of the vapor is .00507 moles per liter are given in Table I.

TABLE I

Substance	Temperature— absolute at which C = .00507 moles/liter	Entropy of Vaporization
		Calories/degree
Ortho nitroaniline	480 9	16 0
Meta nitroaniline	500 4	15 7
Para nitroaniline	530 4	17 5
Ortho toluidine	401 6	16 4
Meta toluidine	405 1	15 6
Para toluidine	402 4	15 8
Ortho nitrotoluene	416 3	13 6
Meta nitrotoluene	427 2	14 0
Para nitrotoluene	431 5	13 9

It will be noticed that the toluidines and nitroanilines give values for the entropy of vaporization which are much higher than 13.8, which Hildebrand considered the normal value. Therefore, in all probability these compounds form associate or polar liquids. This is not the case with the nitrotoluenes which may be considered to be practically non-polar liquids.

It may not be too much to assume that there could be a relationship between the entropies of substances and their electrical structure, since, as is known, the heat of vaporization and association, dependent upon the polarity of the molecule, are related to its electronic structure. From a thermodynamic consideration it is evident that the entropy, association and heat of vaporization are very closely related. Therefore, a consideration of the electronic structure should, qualitatively, at least, interpret the relationship of the entropies of polar and non-polar compounds.

At the present time there exists no absolute means, or even quantitative relative means of expressing association. The order of association of various compounds can be arrived at through a consideration of their entropies of vaporization (also from the dielectric properties), but a compound may be twice as much associated as another and yet only be a few calory per degree higher in entropy. Yet, while not a measure of the association, the entropy of vaporization does offer a valuable means for comparing the association of various compounds. Hildebrand has shown that all non-associated compounds exhibit the same entropy of vaporization when the concentration of their vapors are the same. This rule is valid even to the critical temperature, for at this temperature the heat of vaporization is zero and the entropy of vaporization for all substances is zero and the entropy of vaporization for all substances is zero at their critical temperature. If the entropies of a series of compounds be compared at the same vapor phase concentration their relative association will be apparent. This is shown in Table I for the nine compounds under discussion.

The Molecule and its Electronic Structure

There are several electric conceptions of the structure of molecules, many of which have had to be radically modified or entirely discarded. The theory of chemical union as is now generally accepted is based on the Bohr conception of the atom under conditions defined by the quantum theory. The chemical aspect of the atom has been amplified by Kossel, Lewis, Langmuir, Stieglitz, Lowry, and Kharasch. However, as applied, there is the polar conception and the partial polar conception. In the polar conception, which is now rather limited to the field of inorganic chemistry, the bonding pair of electrons in a molecule are held by one atom or the other, depending upon which is the negative. In the partial polar conception the atoms comprising the molecule share the bonding pair (or pairs in the case of unsaturated compounds) of electrons between them, the position of the shared electrons shifting toward one side or the other dependent to the relative negativity or positivity of the atoms or groups. Thus it may be seen that there is really no fundamental difference between the polar, non-polar, and partial polar bond, but merely one of degree. If the bonding pair of electrons be held midway between two atoms the bond is of the typical co-valent or non-polar type; if the bonding pair is shifted so that one atom obtains exclusive possession of the electron pair the valency is of the electrovalent or polar type; while if the electron pair is not held by one or the other atom and not exactly midway between, the valence is partially polar in character. According to Dr. Rideal the gradation between polar and non-polar linkage due to a shift in the orbits of bonding or shared electron pairs takes place in quantumized stages.

In the case of the double bonding pair of electrons in the unsaturated compounds there is quite a distinction between the two pairs of electrons. One of these pairs of electrons is assumed of the non-polar type, that is, takes a position midway between two atoms, while the other pair of electrons is a partial polar type which can take up any position between the two atoms and its position will be determined by the relative negativity of the two atoms. This conception was developed by Lowry,¹⁶ and Lapworth and Robinson.¹⁷

If one should consider a saturated hydrocarbon, for instance, ethane; being a non-polar compound the bonding pair of electrons would be midway between the carbon atoms. Now if one should introduce a negative group like chlorine into the molecule, the bonding pair of electrons of the carbon and chlorine would be displaced towards the chlorine atom; and the electron pair between the two carbon atoms would be shifted away from the carbon atom attached to the halogen. That this is the direction in which the displacement takes place may be made evident by considering ethylene; in this compound the electrons forming the two bonding pairs are somewhere midway between the two carbon atoms. If the chlorine derivative of this compound—vinyl chloride—be considered, the position of the extra bonding pair of electrons between the two carbon atoms can be easily ascertained by treat-

¹⁶ Lowry: *J. Chem. Soc.*, 123, 822 (1923).

¹⁷ Lapworth and Robinson: *Trans. Faraday Soc.*, 19, 505 (1923).

ing this compound with a halogen acid. Upon treating vinyl chloride with hydrochloric acid, ethylidene chloride (unsymmetrical dichloroethane) is formed, showing that the bonding electrons shifted away from the carbon atom to which the chlorine is attached, and caused the other carbon atom to assume a relatively electro-negative condition since the positive hydrogen of the hydrochloric acid became attached to this carbon atom. This conception has been used by Kharasch, Stieglitz and others to explain many organic reactions.

A survey of the existing literature on electronic structure revealed but little on the electronic configuration of the benzene molecule. There have been several presentations on the electrical structure of benzene considering it from an electrostatic conception. Lowry,¹⁶ Holleman,¹⁸ Vorländer,¹⁹ Kermack and Robinson,²⁰ Lapworth²¹ and others, however may have had an electronic conception in mind, but did not publish anything that could be so considered.

However, there are a few investigators who consider benzene and its derivatives from the electronic conception of valence. Notable amongst these are Huggins²² and Crocker.²³

Huggins considers the benzene grouping in the light of Korner's²⁴ centroid structure and briefly reviews the present evidence for and against this structure which is based, to a large extent, on the conjugation hypothesis introduced by Erlenmeyer, Jr.²⁵ This structure agrees well with many properties of benzene especially its X-ray crystal structure. The principal objection to this structure is that it necessarily postulates that ortho and meta disubstituted benzene derivatives should be optically active and as yet no indication of this has been noted though much investigation has been instituted on this problem. Several investigators attempted a separation of the optically active forms by means of bacteriological means, but all their results were negative. Some of the workers on this phase were LeBel,²⁶ Lewkowitz,²⁷ Meyer and Luhn.²⁸ However, Huggins does not consider this sufficient proof against this conception and makes the rather interesting statement that "The objections raised to it are invalid or inconclusive," basing this on the consideration that the optically active isomers could be separated if the proper conditions were known and on the assumption that if they were separated they would rotate the plane of polarized light very little or not at all. Nevertheless the Korner centroid structure,²⁴ which consists essentially of six carbon tetrahedra having

their bases all in one plane and their apexes alternately above and below this plane, does give quite a clear interpretation of the structure and it has been shown that the dimensions are almost exactly those corresponding to graphite. Huggins devotes very little of his discussion to the consideration of the electronic structure, which he considers to consist of six electrons around the center of each tetrahedron and two at each corner of the six hexagon formed by the six tetrahedrons making up the benzene nucleus. However, no evidence is given for this electronic structure and it is not discussed or applied.

Crocker's²³ conception deals with the benzene configuration from a strictly electronic viewpoint. His views agree extremely well with those of Kharasch and Stieglitz and brings the views of Lewis, Langmuir, Conant, and Parson into close agreement. His view may be briefly summarized in this manner—there is a ring of six carbon atoms, each singly bonded, by means of pairs of electrons, to its neighbor on either side, and to hydrogen. The remaining six electrons are placed between the carbons in the plane of the ring thus forming an octet for each carbon atom. Substituents of the hydrogen would cause a shifting in the position of these latter six "aromatic" electrons. The direction and degree of this shift, depends on the electrical nature of the substituent and Crocker considers this shift of the aromatic electrons to be mechanically the same as the shift of the electrons in the unsaturated hydrocarbons as in the illustrative example (ethylene) in the preliminary consideration; i.e., if any one of the aromatic electrons moves from its position midway between the carbon atoms, the electrical equilibrium of the system is disturbed and the others must move in such a manner as to restore it. Thus if a positive group, such as the amino group, which repels the paired electrons, to be introduced into the nucleus to form aniline, the aromatic electrons would be attracted towards the 3 and 5 positions and repelled at the 2 and 4 positions. If a negative group such as the nitro group, that strongly attracts the electron pair be introduced into the nucleus to form nitro benzene the electrons will be attracted towards positions 2, 4 and 6 and repelled at the 3 and 5 positions. Crocker considers that substitution is possible only at those positions where the hydrogens are lightly held, that is, the position where the electrons are repelled. It is seen how well this conception explains the reason why benzene derivatives containing negative group—which causes repulsion of electrons at the meta positions are readily substituted in this position while in the case of compounds like aniline, substitution takes place at the ortho and para positions, since it is at these positions that the positive amino group causes the electrons to be shifted away from the nucleus. Holleman²⁹ has very ably discussed the relation of the various groups to their directive powers in the benzene derivatives and Schwalbe³⁰ has made quite a complete compilation of the data pertaining to this.

This conception seems to give the clearest view of the operation of the forces about the molecule and is in very fine agreement with the known facts.

²⁹ Holleman: "Substituenten in den Benzolkern", (1910).

³⁰ Schwalbe: "Benzol Tabellen" (1903).

If these deductions are now expanded upon and the conception of a type of co-valence introduced this view of the molecule of benzene and its derivatives may be applied to the interpretation of facts with which it appears, at first, to have no connections

As was previously mentioned, it seems quite reasonable to postulate that entropy, molecular association and electronic structure may be interrelated. The association of molecules takes place only in the case of polar molecules, that is in those molecules in which the electrical charges are not balanced or the electric moment is not zero. It is seen that this is also one of the conditions under which compounds exhibit co-ordination values. Thus, it has been suggested by Huggins and by Lewis³¹ that the reason for the association of water, ammonia, hydrofluoric acids and similar compounds can be attributed to hydrogen exhibiting a secondary valence or co-valence under the conditions of the great electric or magnetic moments that exist in the molecules of these substances. This suggestion of bivalent hydrogen has been applied by Latimer and Rodebush³² in the interpretation of the association and structure of ammonium hydroxide. As will be indicated in the succeeding treatment on this subject, the co-valency of the hydrogen may be the factor causing the association of the organic molecules, although it is not necessary to postulate that this bivalent form of hydrogen, if it does really exist, is essential to the explanation of the observed phenomena. It is merely noted as a possible factor in the future development.

Electronic Structure of the Compounds studied

In the substances considered in this discussion there are three groups of atoms, the nitro, the methyl, and the amino group, that enter into all the isomeric relations to each other that are possible in their disubstituted benzene derivatives. These may be considered in terms of relative basicity. In the following treatment, a group will be considered as negative if, when joined to the hydroxyl group, it allows the hydrogen of the hydroxyl to be reactive, such as the nitro or sulphonic acid group, NO_2OH , $\text{SO}_3\text{H.OH}$. Conversely, positive groups such as amino when joined to the hydroxyl allow the whole hydroxyl group to react. It is apparent that from this consideration the methyl group is very weakly negative, since, although in methyl alcohol the hydroxyl may be readily split off, as by the action of hydriodic acid, yet it can in addition have the hydrogen of the hydroxyl replaced by much more positive substances such as sodium and potassium.

From the present knowledge of the electronic structure of benzene it may be represented as in A, Fig. 1. This is essentially that proposed by Crocker²³.

Here the small dots represent the normal bonding pair of electrons between the carbon atoms and are considered to be stationary; the large dots the aromatic or polar electrons, which are the ones that shift under the influence of various substituents; and the small circles represent the bonding pair of electrons between the hydrogen and carbon atoms. These latter electrons

³¹ Lewis: "Valence and the Structure of Atoms and Molecules," 109. (1923).

³² Latimer and Rodebush: *J. Am. Chem. Soc.*, **42**, 1419 (1920).

shift in their positions relative to the character of the substituent and the position of the aromatic electrons. For convenience of illustration the benzene nucleus will be employed as shown by (B) in Fig. 1, where the large black dots represent the aromatic electrons and the position of the hydrogen-

FIG. 1

FIG. 2

FIG. 3

carbon bonding electrons are represented by the small bars at the corners of the hexagon by which is to be comprehended the carbon nucleus and the normal bonding electron pairs. The hydrogen symbol will be omitted.

The effect of the type of substituent group on the aromatic electrons of the benzene configuration has been considered in the earlier part of this discussion. These structures may be illustrated as in Fig. 2. It will be apparent from these figures that the nitro group being a strongly negative group attracts the hydrogen bonding pair of electrons (represented by the bars) towards itself, thus causing the above configuration; conversely the amino group being strongly positive repels its bonding pair of electrons causing the aromatic electrons of the 2 and 6 position to approach the 1 position and in-

ducing the electronic arrangement presented above. In toluene the methyl group is practically neutral or slightly negative and the differences between it and the other configurations are but of degree.

In the compounds chosen for this investigation, all the combinations of the above structures are involved. Besides having a definite effect on the aromatic electrons, each group has a profound influence on the effects of the other group present, which depends both on the type of group and its position in the benzene nucleus. The nine compounds studied are represented in Fig. 3 on the basis of the interpolated conception of the electronic structure introduced in this treatment. An attempt has been made to illustrate the degree of repulsion and attraction of the bonding pairs of electrons by means of the variations in the distances from the nuclei of the bars employed to represent the relative positions of the hydrogen-carbon bonds, and of the aromatic electrons. These are to be considered strictly of a qualitative nature and are to some degree exaggerated, for purposes of illustration the relative effects on the electronic configuration caused by the complex inter-effects of the two substituent groups.

In the nitroanilines there is a strongly positive group and a strongly negative group present. As will be evident from the illustrations in Figs. 2 and 3, the amino group in the ortho and para position to the nitro group would act in such a mode as to greatly exaggerate the conditions already present, that is the electrons would be attracted very powerfully to the 2, 4 and 6 position and very strongly repelled at the 3 and 5 positions. However, in the case of the meta isomer, it will be apparent that the effect of the amino group is opposed to that of the nitro group because the nitro group is attracting the paired electrons away from the nucleus while the amino group is forcing them towards the nucleus. Since this condition exists, the effects of the nitro group will be materially diminished and the configuration altered to one that more nearly approaches that of benzene than that of nitro-benzene or aniline.

There are some differences between the ortho and para configuration that are of importance to note. While the amino group in either the ortho or para position to the nitro group tends to greatly increase the effects caused by the amino group there are differences in degree of this effect between them. The amino group in the para position has a more profound influence in exaggerating the nitrobenzene structure than the ortho amino group. This difference may be accounted for by two considerations. The first, is that the ortho amino group, due to its stereochemical position has a greater effect on the reactive repelled electrons in the 3 position than it has on those in the 5 position and in its effect on the 5 position it is to some extent hindered through having the nitro group in an intermediate position, on one side, between the amino group and the 5 position. The second consideration is a purely chemical one. It has been shown by several investigators, notably Baly, Edwards, and Stewart,³³ Baly, Tuck and Marsden,³⁴ Hantzsch³⁵ and Kharasch, Lom-

³³ Baly, Edwards and Stewart: *J. Chem. Soc.*, **89**, 517 (1906).

³⁴ Baly, Tuck and Marsden: *J. Chem. Soc.*, **97**, 581 (1910).

³⁵ Hantzsch: *Ber.*, **43**, 1668 (1910).

men, and Jacobsohn,³⁶ that there is marked tendency for the nitro group and amino group, when in the ortho or para positions to each other or to other reactive groups, to react to form quinone derivatives of the nitronic acid and quinone-dioxime types. This effect will be subsequently discussed. Now it is apparent that in a reaction of this nature, which can be considered as forms of neutralization, the effects of the substituents on the electronic configuration would be such as to cause a change of the electronic arrangement in the direction of the non-polar type of compound; also it is apparent that in an intramolecular rearrangement or reaction, (may also be considered as an intermolecular reaction), the reacting groups would have a much greater tendency to react if they are adjacent to each other as in the orthonitroaniline, than if they were relatively greatly displaced as in the para derivative. These two considerations are believed to be sufficient to account for the difference in electronic configuration and therefore the relative association between the ortho and para nitroaniline. In fact it is easily conceived that the rearrangement producing a partial electrical neutralization in the ortho derivative, may be so great as to cause this compound to, electronically, approach quite close to the meta arrangement.

Electronic Structure and Molecular Association

From the consideration of the previously discussed hypothesis of Huggins and Lewis, it is conceivable that the greater the electronic moment of a molecule, that is, the more labile its electronic charges, the more polar it becomes and therefore the more associated. In the nitroanilines, as is evident from this postulate, the para isomer is very much more polar than the ortho or meta, and the ortho nitroaniline is more polar than the meta. Since the polarity is the cause of association of molecules, the higher the polarity the greater the association. As was explained in the preceding section, the association of a molecule is related to the entropy of vaporization of that substance. Therefore, it may be stated, that the polarity and entropy of a molecule are directly related.

Reference to Table I indicates that the entropy of vaporization of the isomeric nitroanilines are in fine agreement with the conclusions of the preceding discussion of their relative polarities. As is required by the electronic conception that is advanced in this treatment, the para nitroaniline should have a far greater entropy of vaporization than the ortho and meta isomers since its polarity is so much greater; likewise since the polarities of the ortho and meta nitroanilines are not greatly dissimilar the values for the entropies of vaporization are relatively close together for these two compounds. This agreement gives very substantial indication that the premises assumed for the structure of these compounds are correct.

In the toluidines, there are present a strongly basic or positive group and a very weak negative group. As would be supposed the methyl group has a relatively small though appreciable effect. Considering the electronic structure as that of aniline, it is readily noted that a negative group would tend to

³⁶ Kharasch, Lommen and Jacobsohn: *J. Am. Chem. Soc.*, **44**, 793 (1933).

intensify the polarity of the initial electronic configuration if it were in the ortho or para position. Therefore, the ortho and para toluidines should be more polar, hence more associated, and should have a higher entropy of vaporization than the meta.

In the ortho toluidine the effect of the methyl group on the electrons of the 6 position, is transmitted and increased by the amino group thus causing the electrons of the 6 position to be somewhat more displaced than those of the 4 position. In the para toluidine the two electron pairs ortho to the amino should be equally repelled from the nucleus; thus it is evident that the ortho toluidine should be more polar than the para compound and therefore have a higher entropy of vaporization. As may be ascertained from the table of the entropies of vaporization, the above conclusions are justified.

The precepts, as presented for the toluidines and nitroanilines, should apply to the nitrotoluenes as well. The validity of this is observable from the following consideration and from the representation of these compounds in Fig. 3. Since both the nitro and the methyl group are negative it will be at once evident that when they are in a meta position to each other the electronic configuration originally present in the nitrobenzene will be somewhat intensified and therefore the meta nitrotoluene will be the most polar mononitrotoluene. Since the effect on the electron displacement in the nitrotoluenes is due almost entirely to the nitro group the methyl group in the para position will have little or no effect on the electron displacement of the positions meta to the nitro group and therefore the para nitrotoluene is but slightly less polar than the meta isomer. In the ortho nitrotoluene the effect of the nitro group is diminished by having to be exerted through the methyl group which is in a position such as to oppose the forces of the nitro group, at least for one position (ortho to the methyl). As in the case of the ortho nitroaniline there may be some intramolecular rearrangement or reaction. This will subsequently be referred to. The nitrotoluenes which, it is to be recalled, are polarized but slightly if at all, are nevertheless in accord with the principles that are applicable to the other compounds.

Thus it is evident that the electronic structures of these compounds are related to their association and polarity and the sequence and relative degree of this association is in agreement with the values derived from experimental evidence.

Effect of Intramolecular Reactions

From a consideration of the electronic configuration alone, one would deduct that the ortho nitroaniline and the ortho nitrotoluene would be more highly associated and have a higher entropy than they actually exhibit. As has been indicated the lower degree of polarity of these compounds is thought to be due to some intramolecular reaction. There is at the present time much speculation on this type of reaction and the constitution of these intramolecularly condensed compounds that are known as "meriquinoids." These were first observed by Wurster³⁷ in 1879 and then studied by Bernthsen,³⁸

³⁷ Wurster: Ber., 12, 1803, 1807, 2071 (1879); 13, 3195, 3217 (1880).

³⁸ Bernthsen: Ann., 230, 162 (1885); 251, 11, 49, 82, (1889).

Willstätter, and Pfannenstiel,³⁹ and Willstätter and Piccard,⁴⁰ who concluded that these compounds were a class of quinone derivatives of a semiquinonemide type. It has been suggested by Kehrman,⁴¹ Kaufmann,⁴² and Meyer⁴³ that the two reactive components exist in a condition of dynamic equilibrium with reference to each other which they call "isorropesis" or the make-and-break in the linkages of the residual valencies. While this term is usually applied to an intramolecular condition, it may be extended to include an intermolecular condition such as is represented in the recurrent making and breaking of linkages between different molecules.

It may therefore be safely assumed that in ortho nitroaniline and probably ortho nitro-toluene there is a great tendency for an isorropesic condition to exist and from a consideration of their electronic arrangements and their entropies of vaporization one may reasonably presuppose that such condition does exist.

Summary

A relationship between the electronic configuration and association as derived from vapor pressure measurements is shown to exist. This has been applied in the interpretation of the variations in the entropies of vaporization of the isomeric nitroanilines, mononitrotoluenes and toluidines. The significance of the relations has been considered.

MUTAROTATION IV. CONSECUTIVE REACTIONS IN THE MUTAROTATION OF GLUCOSE AND GALACTOSE

BY FREDERICK PALLISER WORLEY AND JOHN CLARK ANDREWS

Experimental investigation of the mutarotation of glucose has hitherto failed to afford any definite indication that the process is other than the direct attainment of simple equilibrium between α glucose and β glucose, represented by the equation

The reaction appears to be strictly unimolecular from each end, but since the velocity is enormously affected by alkalis and to a smaller extent by acids, the catalyst should appear on each side of the equation, the reversible reaction being probably bimolecular. In the polarimetric method of following the course of the change, optical rotations of the substances present are taken as proportional to their concentrations. It is found that the rate of change of rotation at a given time is proportional to the difference between the rotation at this time and at equilibrium, this ratio being the velocity coefficient. It can easily be shown that this should be the case if the reaction is a reversible unimolecular change or a reversible bimolecular change in which the second reactant on each side of the equation remains constant. Furthermore, the velocity coefficient of mutarotation of α glucose and β glucose determined in this manner under similar conditions should be the same, viz. $K_1 + K_2 = K$.

If in the reversible reaction

the initial concentrations of α and β glucose be a and o respectively, and if the amounts of α glucose converted to β glucose at time t and at equilibrium be x_t and x_∞ respectively, then at time t

$$dx/dt = K_1 (a - x_t) - K_2 x_t$$

at equilibrium

$$K_1 (a - x_\infty) = K_2 x_\infty$$

$$x_\infty = \frac{K_1 a}{K_1 + K_2}$$

at time t

$$\frac{dx/dt}{(a - x_t) - (a - x_\infty)} = \frac{dx/dt}{x_\infty - x_t}$$

$$\begin{aligned}
 &= \frac{K_1(a - x_t) - K_2x_t}{\frac{K_1a}{K_1 + K_2} - x_t} \\
 &= K_1 + K_2
 \end{aligned}$$

Hence in the polarimetric method of following the mutarotation

$$K_1 + K_2 = \frac{1}{t_2 - t_1} \log \frac{(\alpha_1) - (\alpha_\infty)}{(\alpha_2) - (\alpha_\infty)}$$

in which α_1 , α_2 and α_∞ are the rotations at t_1 , t_2 and t_∞ .

The velocity constant as usually determined should thus be $K_1 + K_2$ in the case of both α glucose and β glucose.

It has been amply shown that the reaction over the very large portion investigated is strictly unimolecular and that the velocity coefficients of mutarotation of α glucose and β glucose are identical under similar conditions.¹

It has also been shown that if α and β glucose be mixed in the proportion calculated to be present at equilibrium both in the case of water and of methyl alcohol, on the assumption that the reaction is expressed by the above simple equilibrium, and dissolved in the respective solvents, there is no detectable change of rotation after dissolution² indicating that there is no third substance present at equilibrium capable of detection by the physical methods employed.

These considerations, however, do not eliminate the possibility of mutarotation proceeding in two, or more stages, but show that if an intermediate substance is formed, the rate of its transformation into α and β glucose must be very much greater than that of its formation. If the velocity of transformation were a large multiple of that of the reverse change, there would be only a small percentage of the sugar in the intermediate form at equilibrium, and, since the physical methods employed in the mixture experiments are dependent on the *difference* between the physical properties of the intermediate form and those of the mixture of α and β glucose from which it is formed, this small amount of a third substance would not be detected in the experiments. Its formation should, however, be indicated by the course of the reaction at the beginning of mutarotation.

If we assume that starting from α glucose, the original concentration is a and that at time t the amount left is $a - y$ and the amount of the intermediate substance X formed is x , the concentration of β glucose will be $y - x$ according to the equation.

¹ Roux: Ann. Chim. Phys., 30, 422 (1903); Hudson and Dale: J. Am. Chem. Soc., 39, 320 (1917); Andrews and Worley: J. Phys. Chem., 31, 882 (1927).

² Roux: Ann. Chim. Phys., (7) 30, 422 (1903); Rüber: Ber., 56, 2185 (1923); Andrews and Worley: J. Phys. Chem., 31, 1880 (1927).

From the fact that there is no detectable amount of an intermediate substance present at equilibrium, it follows that $K_2 + K_4$ must be large in comparison with K_1 and K_3 . Let $K_1 + K_3 = k$. The rate of formation of X is given by

$$\begin{aligned} dx/dt &= K_1(a - y) + K_3(y - x) - (K_2 + K_4)x \\ &= K_3(a - x) + k(a - y) - (K_2 + K_4)x \end{aligned}$$

If $k = 0$, dx/dt becomes zero, x reaching a maximum when

$$K_3(a - x) = (K_2 + K_4)x$$

thereafter x remains constant during the remainder of mutarotation until equilibrium is attained.

If k has a positive or negative value, dx/dt becomes zero and x reaches a maximum when

$$K_3(a - x) + k(a - y) = (K_2 + K_4)x$$

If k is positive x will reach a maximum and thereafter decrease as $a - y$ decreases until equilibrium is reached. If, however, k is negative x will increase as long as $a - y$ decreases, that is, during the whole course of mutarotation.

Consider first the simpler case when $K_1 = K_3$. In the mutarotation of either α glucose or β glucose, the concentration of the intermediate substance will increase from zero to a maximum and thereafter be constant during the remainder of mutarotation, the concentration at maximum depending on the ratio of K_3 to $K_2 + K_4$. Accompanying the gradual increase in the concentration of the intermediate substance, whether we start from α glucose or β glucose, there will be a corresponding increase in the rate of formation of the other isomer until the maximum amount of the intermediate form is present. There will thus be initially an apparent retardation in the rate of mutarotation which will be the same whether we start with α glucose or β glucose.

If K_1 is not equal to K_3 , there will also be an initial retardation, but the effect in the case of α glucose will be somewhat different for that in the case of β glucose. If $K_1 > K_3$, the retardation with α glucose should be more pronounced, but of shorter duration than with β glucose and vice versa.

In the polarimetric method of following the course of mutarotation, an additional complication is introduced by the optical activity of the intermediate substance. The retardation will be modified according as the intermediate substance has a high or a low rotation. If high, the retardation in the case of α glucose will appear more pronounced, while in the case of β glucose, it may be diminished, obscured, or possibly converted into an apparent acceleration. In the light of the above analysis of the problem, various initial effects may be expected according as K_1 is greater than, equal to, or less than K_3 , and according as the intermediate substance has a high or low rotation.

In the case of galactose, Riiber¹ followed the course of mutarotation by methods dependent on (1) the change in volume of the solution and (2) the

¹ Ber., 59, 2266 (1926).

change in refractivity as well as by (3) the polarimetric method. By the dilatometer method he found that in the initial stages of mutarotation of α galactose the reaction departed considerably from the unimolecular nature of the subsequent part of the mutarotation. There was, however, no observable departure in the case of β galactose. He assumed the formation of a third or intermediate form of galactose and by an elaborate mathematical investigation, arrived at the four velocity constants and the proportions of the three forms present at equilibrium. By the refractometric method, a slight and doubtful divergence from the subsequent uniform unimolecular nature of the reaction was observed in the initial stages. By the polarimetric method no departure was indicated. In the case of the glucose, Riiber found no evidence for the existence of an intermediate form, the reaction appearing regular from the beginning when treated as a simple unimolecular balanced action.

Mutarotation of Glucose and Galactose at 0°C

It is possible that at 25° any retardation in the mutarotation of glucose may occur only in the short interval after dissolving the sugar when the polarimetric readings are not taken or are discarded owing to the possibility of the temperature not having become constant. In order to examine the initial stages more minutely, we have carried out experiments at 0°C with α and β glucose and α and β galactose in aqueous solution, the velocity of mutarotation being very much less at this temperature than at 25° , and any initial retardation correspondingly protracted.

The polarimetric tube was imbedded in crushed ice in a box considerably longer than the tube. Extension tubes attached to the polarimetric tube passed through holes in the box. The sugar and the water were mixed at 0°C and quickly transferred to the polarimetric tube imbedded in the crushed ice. Readings were taken at frequent intervals after mixing and afterwards at longer intervals. In Tables I-IV are given the results of four typical experiments made with α and β glucose and α and β galactose respectively. Each rotation is the mean of five readings taken at intervals of ten seconds.

The results of the above four experiments are shown graphically in Figs. 1 to 3. In Figs. 1 and 2 the observed rotations are plotted as ordinates and the times as abscissae, the curves thus representing the course of mutarotation as indicated by the change in optical rotation. In the case of both α and β galactose (Fig. 1) there is an initial flattening of the curve indicating an initial retardation which is more pronounced in the case of the β sugar. In the case of glucose (Fig. 2) there is an initial flattening or retardation in the case of α glucose, but an initial acceleration in the case of β glucose.

In Fig. 3 the logarithms of the differences between the specific rotations at the various times and the specific rotation at equilibrium are plotted as ordinates against the times as abscissae. In order to plot the curves in one diagram, the logarithms of α galactose and α glucose have been diminished by 0.10 and 0.17 respectively and those of β galactose increased by 0.03 throughout. If the velocity of mutarotation be in accordance with the re-

quirements of a unimolecular balanced action, as has already been found to be the case during the greater part of the mutarotation, a straight line should be obtained, the slope of the line affording the value of the velocity coefficient. This method of expressing the results clearly shows the nature and duration of the initial divergence from the unimolecular character of the change obtaining during the subsequent mutarotation. In the case of α galactose the initial retardation is seen to be followed by an acceleration before the mutarotation becomes regular as expressed by the straight part of the curve, the initial divergence extending for about twenty minutes. In the case of β galactose, there is an apparent complete arrest of mutarotation for about thirty minutes, after which the action becomes normal. The slope of the two curves when they become straight lines is approximately the same, that for α galactose, however, being slightly the greater. In the case of α glucose, the retardation extends over about fifteen minutes before the curve becomes a straight line. The initial divergence in the case of β glucose is an acceleration extending for about twenty-five minutes, the subsequent straight part of the curve having the same slope as that of α glucose.

The possibility of the initial divergence being due to the temperature not having become constant has been considered, but although a portion of the divergence may be due to a temperature effect, it appears that such portion must be small in comparison with the total effect observed. Four or five experiments were carried out in each case and the general form of the curves for each sugar found always to be the same. We consider that the different characters of the initial divergences are to be explained principally by the magnitude of the rotation of the intermediate substance and by the relation of K_1 to K_3 . These results we regard as definite evidence against mutarotation being a simple unimolecular balanced action between the α and the β sugar. They appear to be in agreement with the requirements of an action which proceeds by the formation of an intermediate substance and represented by—

in which the rate of formation of X is very slow in comparison with the reverse changes. Although the possibility is not excluded of mutarotation proceeding in more than two stages with the formation of more than one intermediate substance, there is no evidence that more than one intermediate substance is formed, and it is reasonable to assume provisionally that one only is present. In the case of galactose, the more prolonged initial divergence from the uniformity of the subsequent course of mutarotation compared with that of glucose, considering also the greater speed of mutarotation of galactose, indicates that the difference between the rate of formation of the intermediate substance and the reverse changes is considerably greater in the case of glucose than in that of galactose, with the result that the amount of the intermediate form present during mutarotation and at equilibrium will be considerably greater for galactose than for glucose.

Temperature Coefficient of Velocity of Mutarotation

The velocity coefficients at 0°C and 25°C are given in Table V. The values at 0°C being the means of five determinations in the case of α glucose and α galactose and four determinations in the case of β glucose and β galactose.

	TABLE V		
	0°C	25°C	$\frac{K_{25}}{K_0}$
α glucose	0.00073	0.0096	
β glucose	0.00073	0.0096	
mean	0.00073	0.0096	13.2
α galactose	0.00092	0.0134	
β galactose	0.00090	0.0134	
mean	0.00091	0.0134	14.7

From these results the velocity of mutarotation for a rise of 10°C is increased 2.8 times for glucose and 2.9 times for galactose. At 25° the initial divergence would be completed within the first two minutes after mixing. This accounts for the divergence not being detected at 20 or 25° by the polarimetric method.

In the mutarotation of glucose in methyl alcohol, since the rate is very much reduced, it should be possible to observe an initial divergence at 25° corresponding to the divergence in aqueous solution at 0°C. An experiment carried out with α glucose in methyl alcohol at 25° C has shown a retardation extending over about an hour. We are investigating the initial mutarotation of β glucose in methyl alcohol. It is possible that the partial or complete "arrest" of mutarotation which has sometimes been observed¹ is to be explained in the same way as the initial divergence we have observed in the above experiments.

Summary

1. The mutarotation of α and β glucose and α and β galactose in aqueous solution has been examined by the polarimetric method at 0°C in order to investigate the initial stages of the action.

2. It is found that in each case there is an initial divergence from the subsequent uniform unimolecular nature of the change. In the case of α galactose, there is an initial retardation followed by an acceleration; in the case of β galactose mutarotation appears completely arrested for about thirty minutes. In the case of α glucose an initial retardation is observed and in the case of β glucose an initial acceleration.

3. It is claimed that these divergences show that mutarotation is not a simple unimolecular balanced action, but are in agreement with the requirements of an action proceeding in two stages with the formation of an intermediate substance, the different characters of the divergence being due to the magnitude of the rotation of the intermediate substance and the relative values of the velocity constants.

¹ Lowry and Richards: J. Chem. Soc., 127, 1385 (1925); Faulkner and Lowry: 1926, 1938.

4. The temperature coefficients of the velocity of mutarotation of glucose and galactose have been determined. The velocity constant for glucose is increased 2.8 times and for galactose 2.9 times for a rise of 10°C .

We desire to express our indebtedness to the Royal Society for a grant to one of us (F.P.W.) towards the cost of polarimetric apparatus, and to the N. Z. Department of Scientific and Industrial Research for a National Research Scholarship which enabled one of us (J.C.A.) to take part in the investigation.

NEW BOOKS

Colloids By H. R. Kruyt. Translated by H. S. van Klooster. 23 × 15 cm; pp. xi + 262. New York: John Wiley and Sons, 1927. Price: \$3.50. In the general introduction the chapters are entitled: preliminary consideration of colloidal systems; boundary phenomena; capillary electrical phenomena. Part II deals with suspensoids and the headings of chapters are: stability of suspension; charge and stability; constitution of the double layer; kinetics of flocculation; optical properties of suspensoids; properties of suspensoids from the kinetic point of view; formation of suspensoid sols; historical outline of the development of the theory of suspensoids. Emulsoids are taken up in Part III with chapters entitled: general properties of emulsoids; stability of emulsoids; protein sols, osmotic phenomena; gels. There is a final chapter on special sols which constitutes Part IV.

In spite of the fact that dyeing—a typical adsorption process—may take a very long time at room temperatures and some minutes even at the boiling-point, Kruyt states definitely, p. 34, that adsorption equilibria are reached quite rapidly.

“Robert Marc has found that the adsorption of starch by powdered crystals is 90 per cent complete within a few seconds. In general, adsorption equilibria of this kind are established in a few minutes. Whenever we meet with an adsorption reaction that does not reach a final value within this period of time, we can be reasonably sure that it is not a simple one. For instance, in the adsorption of oxalic acid by charcoal, the condition reached after ten minutes apparently does not represent complete equilibrium since the concentration of the liquid continues to decrease, although very slowly, for several hours. Further investigations have shown that the adsorbed oxalic acid reacts with dissolved oxygen, and that this process is catalytically accelerated in the adsorption layer. This combination of adsorption and chemical reaction occurs frequently. Pure adsorption processes are characterized by a rapid attainment of the final state of equilibrium.”

“The phenomena observed when a sol is flocculated by means of an electrolyte such as AlCl_3 agree well with the changes in boundary potential. When increasing amounts of AlCl_3 are added to a negatively charged sol of mastic, we notice that small concentrations cause flocculation, somewhat higher concentrations produce another stable sol of opposite sign, i.e., positively charged, while still higher concentrations bring about another flocculation. . . . We have, therefore, first a non-flocculation zone, next a primary flocculation zone, then another non-flocculation zone in which the sol has the opposite sign and, finally, a secondary flocculation zone.

“This phenomenon is designated as an *irregular series*. It will always occur when the potential-lowering effect of the cation is far in excess of the potential-raising effect of the anion. This lowering effect may be due either to a high valence of the ion or to a high degree of adsorbability. Polyvalent cations give, therefore, irregular series when they are combined with monovalent anions. But monovalent *organic* cations act in the same way. For instance, strychnine nitrate, as well as new fuchsin, yields an irregular series with As_2S_3 sol, and AgNO_3 with the sol of HgS , because in each case the cation is strongly adsorbed,” p. 85.

“In recent times, chemical arguments have been advanced which seem to indicate that the cellulose molecule is not exceedingly large. It has been erroneously assumed in organic chemistry that n , in the formula $(\text{C}_6\text{H}_{10}\text{O}_5)_n$, is large; in reality, this quantity is completely unknown since we lack the means of determining the molecular size of a non-volatile and insoluble (i.e., non-molecularly dispersible) substance. From the researches of Bergmann and those of Pringsheim, one gains the impression that there is a possibility of obtaining cellulose temporarily—although only under unstable conditions—as a monomolecularly dispersed substance, in which case $n = 1$ according to the ebullioscopic method. These chemical investigations are thus a confirmation of the concept developed here, viz., that sols are polymolecularly dispersed particles. Other experiments of Bergmann prove that the development of the organic chemistry of proteins is proceeding in the same direction,” p. 176.

"An important difference between suspensoids and emulsoids lies, as we have seen, in the fact that the latter, when deprived of their electric charge, do not flocculate. This is exactly the point which has led to a separation of the statics of emulsoids from that of suspensoids.

"In order to explain this difference, we must look elsewhere for a suitable hypothesis which can be tested experimentally. Evidently, emulsoids have a *second stability factor* which prevents the flocculation of the unchanged particles. Remembering that the condition of non-flocculation signifies a probability of adhesion not largely deviating from zero, we realise that this second factor, which keeps the colloiding particles from permanently uniting, must be of a different nature. Since the characteristic difference between suspensoids and emulsoids is due to the hydration of the particles, we immediately assume that it is the film of water which furnishes a second protective factor. In other words, emulsoid particles may be protected against flocculation both by their electric charge and by their hydration. When we have at our disposal a means of eliminating hydration, we can readily verify this assumption, p. 180.

"We have already seen that the addition of minute quantities of an electrolyte to a starch or an agar-agar sol removes the charge but not the stability. On adding alcohol to such a discharged sol, one observes an immediate flocculation. This proves, therefore, that we are dealing, in every case, with two stability factors but that it is immaterial in which order they are removed. The removal of one can be accomplished without evident effect, but the removal of both inevitably causes flocculation," p. 181.

"It has been shown that the power of salting out depends on both the nature of the cation and that of the anion. The different cations can be arranged in a series of decreasing precipitating power, from left to right, when used in equal molecular concentration. A similar series exists for anions. These series are called *lyotropic series*. Cation series: Li-Na-K-Rb-Cs and: Mg-Ca-Sr-Ba. Anion series: SO_4 -Cl-Br- NO_3 -I-CNS

"These lyotropic series are not only met when emulsoids are salted out but are also characteristic of a number of other physico-chemical phenomena. The effect of neutral salts on the *rate of inversion of cane sugar* and on other reaction velocities is determined by the order of the lyotropic ionic series. The same sequence is noticed in the displacement of the *maximum density of water* (at 4°); in the change in *solubility of non-electrolytes*, for instance, that of urea in water; and in the lowering of the *surface tension of water*. In the subsequent chapters we shall consider still other properties that are related to these lyotropic series," p. 183.

"We saw previously that the dehydration effected by alcohol results from the mass-law equilibrium between alcohol and water. Tannin, on the other hand, is a substance which lowers the surface tension considerably; in other words, it is strongly adsorbed. Hence, the large effect in small concentrations is presumably due to the adsorption of tannin by the colloidal particles.

"That this is really the case can be proved in the following manner: When another compound that is capable of exerting a displacing action is added to an agar-agar sol treated with tannin, the colloidal particles are freed, at least partly, from the adsorbed tannin; and, consequently, the emulsoid properties must return. Curiously enough, we can use, for instance, alcohol for this purpose. Investigation has shown that alcohol added in small amounts to an agar-agar sol, that has been dehydrated by tannin, increases the relative viscosity and brings back the property of gelatinizing, whereas the addition in quantities of about 50 per cent again prevents the setting of the sol as a result of the dehydration by alcohol," p. 186.

"Let us discuss, first of all, the viscosity of a gelatin solution as a function of the hydrogen-ion concentration. Loeb made an unusually extensive study of this relationship. It is to his credit that he paid particular attention to the hydrogen-ion concentration of the intercellular liquid and did not confine his investigations to the concentration of the added acids and bases. In the course of his researches, he gradually dropped his early view that gelatin solutions were true electrolyte solutions; and the present writer is convinced that, had his untimely death not interrupted his work, he would before long have arrived at the theory

that is here propounded. His last experiments on the cataphoretic velocity of gelatin pointed clearly in this direction. Probably he would have been forced to retract erroneous statements regarding colloid chemistry made in previous years. As a matter of fact, he had already deserted his original viewpoints a number of times in the period from 1918 to 1923," p. 195.

"Briefly summarizing our ideas regarding the stability of suspensoids and emulsoids, we arrive at the following conclusion, which is best illustrated by means of four characteristic sols: (1) gold sol, (2) tin oxide sol, (3) agar-agar sol, (4) gelatin sol.

"The stability of these sols is dependent on the electric charge, on hydration, or on both. In the case of the first two sols there is practically no hydration; they are suspensoids, the stability of which is solely a function of their electric charge. The last two sols can exist on the strength of their considerable hydration alone, although they are generally stabilized by both charge and hydration.

"Between sol 1 and sol 2 there exists a difference already extensively discussed. The gold atoms in the periphery of the gold particle are not able to form a double layer of their own accord, but require an outside peptizing electrolyte in order to obtain a charge. The flocculation of such a sol is in perfect accordance with Freundlich's theory. The tin oxide sol, however, has a double layer, the inner coating of which is furnished by the sol itself. Since this inner coating may be positively or negatively charged, depending in the stabilizing electrolyte, two kinds of sol are possible.

"About the same difference exists between the two emulsoid sols mentioned above. The carbohydrate agar-agar is in itself little suited to the formation of a double layer. Traces of an electrolyte (possibly derived from the ash content) build up the double layer, and the phenomena of discharge are governed exclusively by the theory of Freundlich. The gelatin sol, on the other hand, possessing ionogen molecules, can form a double layer either in an acid or in an alkaline medium, thus greatly resembling the tin oxide sol.

"Hence, there is this difference between sols 1 and 2, and likewise between sols 3 and 4; viz., that sols 1 and 3 derive their double layers from absolutely extraneous constituents whereas in the second and the fourth cases one constituent of the double layer originates in the particle itself," p. 200.

"Loeb made numerous osmotic measurements, using the gelatin sol, and with the aid of a line of reasoning advanced by Procter and Wilson, he compared the results obtained with the data derived from an application of Donnan's theory. The agreement was obviously very good since his case was the one just mentioned. Loeb inferred, quite erroneously, that his system belonged to the type exemplified by Congo red, i.e., an electrolyte in true solution one ion of which—viz., the gelatin ion—cannot pass through the membrane. General objections to this view have already been developed. Here, too, we are justified in rejecting the conclusiveness of the arguments in the field of osmotic measurements for the simple reason that the agreement with Donnan theory holds just as well for a colloid in adsorption equilibrium with a peptizing electrolyte as it does for an electrolyte of the Congo red type," p. 207.

"Gelatnizing is the agglomeration of hydrated particles which retain the remaining water inside the capillary spaces between them. This agglomeration occurs, for sols of the type of aluminum oxide, simply by electrolyte-flocculation, and is, consequently, irreversible; whereas in cases of temperature-gelatnizing, the process takes place reversibly in some manner as yet unexplained," p. 217.

"Lyotropism is probably not a hydration pure and simple, but one that orients the dipoles of water. This explains at once, why, in the case of proteins, the lyotropic series are reversed when the charge of the protein changes from positive to negative. Here, too, the similar or dissimilar location of the hydrated water determines the order of the lyotropic phenomena." There is no reversal of the series with fibrin or gelatine.

On p. 245 the author says that water-in-oil emulsions are, as a rule, very viscous, or, to express it more correctly, plastic. This statement is true only for water-rich emulsions of this type.

The Chemical Coloring of Metals. By Samuel Field and S. R. Bonney. 21 × 14 cm; pp. xix + 264. New York: D. Van Nostrand Company, 1926. Price: \$4.00. The book is written avowedly for the craftsmen and the chemistry is, therefore, distinctly elementary. It gives a wealth of material to the chemist who may be interested in working out the theory of the processes. The quick methods of producing patines tend to give a transparent color like a wash. The patines produced in the course of centuries are usually more solid in color. This difference cannot be necessary and should not exist.

Incidentally, there are some puzzling chemical problems. Why should clean copper turn a rich rouge-brown color, p. 148, when boiled with a cupric chloride solution and why should sunlight give this a bluish shade, p. 134. Iridescent colors on zinc are obtained by heating with an alkaline copper tartrate solution, p. 205. "This is another of the blue organo-metallic compounds of copper. The solution is used at 110° F. and on zinc a succession of shades is produced, viz., coppery shade, yellow, light brown, crimson, blue, purple, pale purple, light green and finishing with light crimson. These shades are beautiful but not uniform. They give an iridescent effect. The cold solution works slowly, but is easily controlled. The warm solution works more rapidly, but is more difficult to control."

"It is about sixteen years since one of the authors was approached by a firm of telephone manufacturers to nickel-plate aluminum telephones. A refusal to undertake the work could not be taken as the order for the nickel-plated goods had been accepted, some of which were required for steamships and yachts. The nickel-plating was therefore undertaken on the understanding that not more than eighteen months' service could be expected or guaranteed. The work was done, and in less than this stipulated time the fittings had to be removed and were not replaced by similar work. Sea air has a most detrimental effect on aluminum. In the case of these fittings, the nickel-plate began to blister, especially where handled, and soon peeled.

"The at first apparent success of the plating brought forth many enquiries and other types of aluminum ware were tried. The writer has before him a candle-stick stem which was nickel-plated sixteen years ago. The plating is not perfect now, minor imperfections, consisting of pimples of the size of a pin-head, being obvious. The cost of the work was, however, prohibitive," p. 226.

Walter D. Bancroft

Practical Physics. By T. G. Bedford. 22 × 14 cm; pp. x + 425 with 225 figures. London: Longmans, Green and Company. Price: 10 shillings, six pence. This text book of Laboratory Physics has been compiled from the manuscript notes in use in the author's classes at the Cavendish Laboratory, Cambridge, and takes shape as a result of long experience of laboratory practice. The standard attained is well in advance of intermediate work though not covering all the ground for the bachelor of science degree in Physics. The course would be admirably suited to students taking physics as subsidiary to an Honours Chemistry degree.

The book opens with a short introduction on the use and care of apparatus, methods of observation and recording of results. The part dealing with the experiments themselves is classed under the usual headings of mechanics and properties of Matter, Heat, Light, Sound, Magnetism and Electricity. The grouping of the experiments under these sections might perhaps be improved in one or two instances. For example, the optical lever should naturally appear with other instruments for measuring small distances instead of under the laws of reflection, but where a good index is provided this point is relatively unimportant.

An introduction to each experiment gives a short résumé of the theory concerned with it. Such brief deductions must necessarily begin with the phrase "it may be shown that . . ." and this point of departure is in every case suitably chosen; the deductions given being namely those connected directly with the practical side of the problem.

Descriptions of standard apparatus, such as spectrosopes, types of galvanometers, etc are confined to the general principles involved; the details of construction, which necessarily differ widely in different patterns, being left for explanation by the demonstrator. In

many cases however where special types of apparatus are described which could suitably be made in a laboratory workshop, the dimensions and construction are given fully. The section on Properties of Matter is particularly well dealt with in this way.

In some cases representative results of actual experiments are given though these are reduced to a minimum to avoid adding unduly to the size of the volume.

The practical experience behind the book is well shown in the full treatment given to the difficulties likely to be met with and the possible causes of failure of an experiment.

W. W. Barkas

Die elektrolytische Wasserüberführung und ihre Bedeutung für die Theorie der wässrigen Lösungen. By Heinrich Remy. Pp. 72. Berlin: Gebrüder Bornträger, 1927. Price: 5.60 marks. This monograph reviews in detail the two methods by which the transference of water during electrolysis has been estimated, viz:— (1) the Nernst method, depending on the introduction of a reference substance and developed on the experimental side notably by Washburn, and (2) the author's own method, involving the use of a diaphragm whereby in effect the middle point of the electrolytic column is mechanically fixed.

In connexion with the second method, which is discussed in greater detail than the first, it appears that, of the various diaphragm materials tested, parchment was by far the most satisfactory. The objection that the electrolytic transference of water would be masked by electro-endosmose is met by the proof that, however significant the latter phenomenon may be in very dilute solutions, it is negligible in electrolyte solutions of normal strength.

As will be readily understood, the two methods in question are both liable to considerable experimental error, and the results obtained for the electrolytic transport of water by one procedure only might be accepted with a certain reserve. The author, however, is able to record a notable agreement between the figures deduced by these very different methods, and there can be little doubt as to the approximate values of the net water transport in solutions of, say, the alkali chlorides.

For the purpose of calculating the absolute quantity of water associated with each ion—the water sheath or envelope—the author proceeds on the assumption that the anilinium and toluidinium ions are anhydrous. On this basis he finds that the envelope of the chlorine ion is approximately 3 molecules of water, and consequently the following values are assigned to the envelopes of the hydrogen and alkali metal ions: H⁺, 1.0; Li⁺, 12.6; Na⁺, 8.4; K⁺, 4.0. The relation of these results to the hydration theory and to modern views on electrolytic dissociation is briefly discussed.

J. C. Philip.

Katalyse mit kolloiden Metallen. By Walter Hückel. 22 × 15 cm; pp. viii + 84. Leipzig: Akademische Verlagsgesellschaft, 1927. Price: 6 marks, unbound. The chapters are entitled: introduction; preparation of colloidal metallic catalysts; colloid catalysis; kinetics of catalysis with colloidal metals; mechanism of the catalytic hydrogenation by means of colloidal metals.

The title is much broader than the actual scope of the book which is limited explicitly to a discussion of laboratory methods, and practically to the work of Paal and of Skita, in other words to laboratory methods with colloidal metals of the platinum group. The real object of the book seems to be to advertize Skita.

The chapter on the mechanism of the catalytic hydrogenation by means of colloidal metals is obscure and unsatisfactory. The author considers that activation of hydrogen may be due: to monatomic hydrogen dissolved either as such or as an ion; to an unstable metallic hydride which decomposes, giving off atomic hydrogen; to an instable metal oxide hydride; or to highly deformed hydrogen molecules. He does not like any of these hypotheses and is apparently sceptical of any activation of hydrogen being important. It therefore becomes necessary to consider the other constituent as activated and he adopts, apparently without proof, Skita's view that activation is due to the formation of a definite chemical compound between the metal catalyst and the unsaturated compound. No reference is made to the views of E. F. Armstrong, presumably because Armstrong did not work with metallic sols. This is a book of which anybody could be ashamed.

VARIATIONS IN THE SURFACE TENSIONS OF SOLUTIONS*

BY S. LAWRENCE BIGELOW AND E. ROGER WASHBURN**

Of all methods for measuring surface tension, the rise of liquids in capillary tubes is the simplest in application and in theory. But frequently it appears to be impossible to reproduce results with reasonable accuracy, while the cause of the trouble is not apparent. On this account the method seems to be falling into disfavor; which is unfortunate.

We undertook to discover, if possible, what some of these hidden difficulties might be and how to guard against them. We were successful in bringing to light some sources of error and in showing that they can be avoided by the application of simple precautions.

In this article we deal mainly with variations in the surface tensions of solutions with time.

Historical

A number of instances of such variations have been recorded in the literature. As early as 1869, A. Dupré,¹ while studying the surface tensions of aqueous solutions of soap, as shown by the vertical height to which fine jets of the solution rose under a definite pressure, conceived the idea that the surface tension of a freshly formed surface was greater than that of older surfaces.

Some twenty years later, Lord Rayleigh,² without previous knowledge of Dupré's work, reached the same conclusion. He measured the surface tensions of solutions of sodium oleate and of saponin, using the vibrating jet method for the freshly formed surfaces and the capillary rise method for the older surfaces. He showed that only in the older surfaces did the soap or saponin produce marked lowering. He believed this lowering to be due to the formation of an insoluble layer or "pellicle" of the organic material on the surface.

S. R. Milner,³ studied the phenomenon with sodium oleate solutions in greater detail. He observed that the fall in surface tension was most rapid at first, and then became slower until finally a constant value was reached. The more concentrated the solution the quicker it reached this constant value. Agitation reestablished the initial value and then the phenomenon repeated itself, but did not always result in the same minimum. He concluded that the decrease in surface tension is caused by adsorption of sodium oleate in the surface until a definite concentration is reached. This would occur quickly with concentrated solutions but might require hours when they were dilute.

* Contribution from the Chemical Laboratory of the University of Michigan.

** The work presented in this paper is taken from a dissertation presented by E. Roger Washburn in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the University of Michigan.

³ *Phil. Mag.*, (6) **13**, 96 (1907).

L. Berczeller,¹ observed a similar decrease in the surface tension of soap solutions with time.

P. Lecomte du Nöuy² is the author of several papers and a book describing instances of surface tensions falling with time. He developed an instrument utilizing the method wherein the force is measured which is required to pull a wire ring off the surface of a liquid. He found, for example, that dog serum added to water or to a saline solution reduced the surface tension gradually. The maximum lowering was reached in from twenty to thirty minutes. Agitation produced an increase in the surface tension but not up to the original value. A second fall ensued but not to so low a value. Repetition gave variations between narrower and narrower limits until finally the surface activity of the serum (its ability to lower surface tension with time) seemed to be completely lost. This lessening of range of variations, this damping effect, must be due to some chemical reaction. Du Nöuy says that all of the effects he observed may be due to one or more of the following causes; chemical change, adsorption in the surface, adsorption by colloids in the liquid, modification of molecular arrangement in the surface.

His results are most interesting, but the systems with which he works are complex and contain too many variables. We need careful studies with the simplest possible systems to establish fundamental principles before we can interpret such results as his with confidence.

He makes the following remarkable statement; "It is only through the ring method that it is possible to observe and study this phenomenon (changing surface tension) as it is the only procedure which permits the measurement of the surface tension of the same layer of liquid at very short intervals." This is manifestly in error. As has been said, S. R. Milner studied the change in surface tension by the capillary rise method which is obviously superior because the surface is not disturbed. Pulling off a ring and replacing it must seriously upset any molecular arrangement in the surface or any concentration gradient established by adsorption. It is indeed surprising that du Nöuy succeeded in obtaining the results he did.

C. E. Davis, H. M. Salisbury and M. T. Harvey,³ using the drop weight method, observed a slight decrease in the surface tension of gelatin solutions with time. Here again it is surprising that the effect was observed, for during the formation of drops the surface is constantly agitated, and we and others have always observed that agitation tends to restore the initial values.

A study of the change of surface tension of solutions of gelatin, casein, albumin and haemoglobin has been made by J. M. Johlin⁴ applying both the drop weight and the capillary rise methods. He found that the longer the time he allowed for each drop to form, the greater the observed change in surface tension. This is quite as it should be, and is convincing evidence that the method is unsuited for anything but qualitative purposes.

³ J. Ind. Eng. Chem., 16, 161 (1924).

⁴ J. Phys. Chem., 29, 270, 897, 1129 (1925).

His results with the capillary rise method were somewhat irregular, especially when wide capillaries were used. Frequent "throbbing" of the meniscus he ascribed to molecular rearrangements in the surface. He observed that often a period of inactivity intervened before the fall began. This lasted but a few seconds with moderately concentrated solutions but grew longer as the dilution was increased. We shall refer to this again in the description of our own work.

It is obvious from this brief review that the phenomenon is of especial interest to physiologists, and with good reason, as it doubtless plays important roles in life processes. Substances such as gelatin, albumin, serum and the like are too indefinite and solutions containing more than one solute are too complex to serve for the establishment of the underlying principles on a satisfactorily convincing basis. A study of the phenomenon as shown by the simple solutions of well-defined chemical compounds is needed, and this we hope we have, in a measure, supplied.

Apparatus and Methods

We adopted as our model the apparatus and methods so ably developed and described by T. W. Richards¹ and his co-workers and endeavored to maintain their standards of accuracy in our work.

We employed the customary methods and had the customary difficulty in selecting a few short lengths of capillary tubing of satisfactorily uniform bore. The range, which careful calibration proved to be uniform in bore, was included between two rings etched in the glass. These tubes were fashioned into capillarimeters of the type shown in Figs. 1, 2, 3, and 4.

In type 1 the wider reference tube is not so wide that the capillary ascension in it can be neglected. The correction is easily applied in most cases, but with constantly changing surface tensions it introduces an inconvenient complication. Therefore we used these only for preliminary work. All of our final measurements were made with capillarimeters of types 2, 3, and 4, the reference tubes of which were at least 38 mm. in diameter. Richards has found that in a tube of this diameter, the central portion of a water meniscus is essentially a flat surface.

The capillarimeters were used in a thermostat which was fitted with plate glass windows front and back. An opaque shield placed between the capillarimeter and the electric light in the rear and just below the level of the large meniscus, as recommended by Richards, aided materially in giving sharply defined images. The cathetometer was graduated to read to 0.05 mm. Its telescope was equipped with a 72 mm. microscope objective, which gave a clear cut, magnified view of the meniscus.

Following the usual precaution, the meniscus was raised and lowered several times and then allowed to fall to its equilibrium position before a first reading was taken. This raising and lowering was produced by blowing or drawing

¹ J. Amer. Chem. Soc., 37, 1670 (1915); 43, 834 (1921).

through a train of calcium chloride, soda lime and cotton connected to the wide arm of the capillarimeter so there was no chance of contaminating the capillary meniscus.

FIGS. 1-4

We designated our capillaries by letters and determined their radii by the usual method of measuring the lengths and weights of threads of mercury, too well known to require description. We also determined their radii by observing the capillary rise of water and substituting in the equation $rh = a^2$, where r is the radius sought, h the true or corrected height to which water rises and a^2 is its capillary constant. Richards and Carver¹ obtained for this constant, at 20° the value 14.877 which we used.

¹ J. Am. Chem. Soc., 43, 834 (1921).

Our results by the two methods checked satisfactorily. For example, we found the radius of capillary C by the mercury thread method to be 0.0169 cm.; by the surface tension method we found 0.0166 as a minimum and 0.0167 cm. as a maximum. The radius of capillary 1P we found by the mercury thread method to be 0.0210 cm. (minimum) 0.0211 cm. (maximum); by the surface tension method we found 0.0211 cm. (minimum) and 0.0212 cm. (maximum). Agreement being so close we felt the surface tension method was sufficiently reliable and preferred it because of the accurate temperature control in the thermostat and because it is so much more easily and rapidly carried out.

The cleaning of the tubes is important. We tried the usual cleaning agents such as aqua regia and chromic acid but finally concluded that the most consistently good results could be obtained by the following procedure. Hot alkaline permanganate solution is drawn through the tube for several minutes, followed by hot hydrochloric acid to dissolve any manganese dioxide formed. Hot water is then drawn through the tube for fifteen or twenty minutes. The tube is dried in an electric oven, the last traces of moisture being removed by drawing dry, filtered, air through the hot tube.

Whether or not a tube is clean can be determined by the behavior of the meniscus before starting an experiment. The meniscus is blown up, through the train already described, and then falls evenly with no indication of sticking, to its equilibrium point. The walls drain apparently dry and no visible droplets remain. It is drawn down and allowed to rise to its equilibrium point. This must coincide exactly with that obtained after falling. The motion must be perfectly smooth and there must not be the slightest flattening or other distortion of the meniscus when in motion. If these conditions are fulfilled the tube is adequately clean.

Making ready for an experiment we poured into the wide arm of the capillarimeter enough of the solution to cause the meniscus in the capillary to stand at some point between the etched lines which marked the uniform section of the tube, and then fastened it vertically in the water of the thermostat. By blowing and suction the meniscus was caused to rise and fall and its behavior studied critically. After enough time had elapsed for the temperature of the apparatus to reach that of the bath, the solution was vigorously agitated and the first reading was made of the meniscus in the capillary and immediately thereafter of the level in the reference arm. Other readings were taken as often as seemed necessary to follow the changes being observed. The meniscus was not agitated after the first reading was made unless so stated in the reports of the results.

In order to abbreviate our report and to facilitate comparisons of results obtained with different tubes, we have omitted the cathetometer readings and capillary heights, but have calculated the corresponding surface tensions in each case according to the formula, $\gamma = \frac{1}{2}ghr(D - d)$, wherein γ is the surface tension, g , the gravitational constant, h , the corrected rise, r , the radius of the tube, and $(D - d)$, the difference between the densities of the liquid and vapor phases. With dilute aqueous solutions this value is almost

exactly the difference between the density of water and that of air saturated with water vapor. And so we used this value; the error thus introduced is negligible as will be shown later.

Solutions of Sodium Oleate. All of our solutions were made up by weight. The sodium oleate was obtained from Mallinckrodt. It was not further purified by us, but was dried at 90° to constant weight. The greater part of

the work which we carried out with this substance was completed in 1924, before the publication of the experiments by J. M. Johlin (loc. cit.). The results which we obtained agree essentially with his, especially as to maximum and minimum values, and we experienced the same difficulty in reproducing exactly any particular experiment carried out with very dilute solutions. The rate of fall which we observed was somewhat slower than that observed by Johlin, though the difference is not great considering the difficulty of working with dilute solutions of this material in fine capillary tubes. Following are the details and results of one of these experiments selected as typical of the many which we did.

Time elapsed	Surface tension	Time elapsed	Surface tension
0	71.0 dynes	65 minutes	52.5 dynes
1 minute	63.7 "	80 "	51.7 "
3 minutes	61.9 "	95 "	50.8 "
5 "	61.0 "	110 "	50.2 "
10 "	59.6 "	170 "	48.2 "
20 "	57.5 "	200 "	47.3 "
30 "	56.0 "	260 "	46.0 "
40 "	54.9 "	350 "	44.7 "
50 "	53.7 "	570 "	42.4 "

These results are plotted as Curve 1.

Solutions of Glycerol. The glycerol was purified by repeated fractional distillation under reduced pressure; the fraction which we used distilled at 200° (uncorrected) under 35 mm. pressure. It is particularly difficult to reproduce an experiment with solutions of glycerol. The reasons for this we do not surely know but we shall offer a possible explanation of the apparently erratic behavior after presenting the experimental data.

Time elapsed	Surface tension	Time elapsed	Surface tension
0	70.7 dynes	179 minutes	63.5 dynes
19 minutes	70.7 "	199 "	62.7 "
34 "	70.7 "	221 "	61.7 "
49 "	70.3 "	231 "	61.2 "
54 "	69.0 "	258 "	60.8 "
87 "	67.8 "	283 "	60.4 "
119 "	67.4 "	298 "	59.8 "
130 "	66.3 "	368 "	58.3 "
143 "	65.5 "	438 "	57.7 "
159 "	63.8 "	528 "	56.0 "

These results are plotted as Curve 2.

After the last reading the solution in the capillarmeter was agitated by drawing it down and blowing it up in the capillary. This caused the surface tension to rise to 62.2 dynes, (point A on the curve). The solution was then carefully withdrawn from the instrument and replaced by an equal amount of water. Under these circumstances the water showed a surface tension of only 58.5 dynes, (point B on the curve), not much different from that of the solution of glycerol which it replaced. Vigorous agitation increased the value,

but only to 63.4 dynes, (point C). The capillarimeter was then carefully cleaned and dried. After this, water in the capillarimeter gave its proper surface tension, 72.6 dynes, as shown by point D on the curve.

This behavior would lead one to believe that during the first part of the experiment glycerol was adsorbed on the glass walls of the capillary and was not all removed, either by agitation or by the removal of the solution.

Another experiment of the same type showed, in addition, the following interesting fact. After the solution had stood in the capillarimeter over night, during which the surface tension fell from 70.6 dynes to 56.9 dynes, the solution was removed and water was substituted. When the amount of water in the capillarimeter was such that the meniscus stood in a part of the tube below that point at which the solution of glycerol meniscus had stood, the surface tension observed was 56.8 dynes. When more water was added, so that the meniscus came to rest at a point above that at which the solution meniscus had stood, the value observed for the surface tension was 72.2 dynes, very nearly the value to be expected for pure water. Since the water was added through the wide arm of the capillarimeter the surface of the meniscus was not changed by the addition, the meniscus was simply raised to a higher level. This tends to confirm the idea that glycerol is adsorbed on the glass walls in that portion of the tube in contact with the solution and is only removed with difficulty by agitation or by washing with water.

At least three later experiments confirmed these results as far as rate of fall is concerned. The time elapsing before the fall started and the effect of agitation, however, were not always the same. Several experiments with solutions of glycerol of the same concentration as that used above, have failed to show any change in more than an hour. In such cases, when the fall did start, the rate with which it progressed was often very much more rapid than that shown in Curve 2. Sometimes when the fall had failed to start for an unusually long time it was caused to start by a gentle agitation. These facts lead one to believe that the phenomenon which is responsible for the fall had been proceeding during the period of inactivity, but that the meniscus for some reason or other was prevented from responding. Something in the nature of a metastable state developed. In these experiments we had every reason to believe that the capillary was clean, but the fact that no change took place could be interpreted as indicating that the tube was not entirely free from foreign matter.

Evaporation of Water. It seemed that the decrease in surface tension might possibly be due to evaporation of water from the meniscus, leaving a more concentrated solution of glycerol, with a resulting lower surface tension. Vigorous agitation should correct this condition, giving a higher surface tension.

In order to determine whether or not this is a probable explanation of the phenomenon we carried out experiments in a type of capillarimeter which could be opened or closed at will, (Fig. 4). When the capillarimeter is closed the atmosphere within it should become saturated with water vapor, there should be no more evaporation and no fall, from this cause at least.

These experiments were carried out at 40° instead of 20° in order that the atmosphere should become saturated with water vapor in less time. The results of such an experiment are shown in Curve 3.*

These results are not in accord with what we should expect if our observed variation were due to the evaporation of water. Closing the system would stop the fall of the meniscus, if the vapor phase is saturated with water vapor,

but it does not. After agitation of the solution in the closed capillarmeter by tilting it to and fro and the consequent restoration of the meniscus to its original condition, the small gaseous volume is surely saturated and there should be no fall at all. But falls occur repeatedly as shown. Not only this, but the fall denoted by part E of the curve is more rapid than that denoted by A, although during A the capillarmeter was open to the air, while, when E was started the instrument had been closed for five hours and forty-six minutes and the vapor phase was surely saturated.

On the other hand the results are in accord with what we would expect if the fall is due to an increased concentration of the glycerol at the interface between the solution and the glass walls, as well as at the solution-vapor interface.

Experiments such as resulted in Curve 2 indicate that if sufficient time be allowed some glycerol will become so firmly adsorbed on the glass walls that even vigorous agitation of the solution does not remove it. The agitation, by tilting, which we used in our closed system experiments, is of necessity comparatively gentle and quite inadequate to remove the adsorbed glycerol;

* We have drawn our curves to scale with care and believe we have included in them all information of interest to a reader. Therefore, we omit the extensive tabulations from which they were constructed.

even when pure water is substituted for the solution the low surface tension persists, presumably due to this adsorbed layer. However, if time has not been allowed for this firm adsorption of glycerol a gentle agitation will bring about uniformity in the concentration of the solution in the capillary. The original high surface tension, characteristic of the homogeneous solution against a clean glass surface, will then be observed. The time required for the glycerol to become thoroughly attached to the walls seems to vary, in the neighborhood of twelve hours being required when working at 20° , and a longer time when working at 40° .

Solutions of Resorcinol. The resorcinol which we used was Mallinckrodt's U.S.P. grade. Solutions of this material show a decreasing surface tension with time. In the results of the typical experiment which we give below we desire to call attention to the effect which the degree of violence of the agitation has upon the nature of the surface tension change which follows it.

The violence of the agitation which causes the surface tension to return to its maximum value after a fall has taken place, has a pronounced effect on the length of time which will elapse before the fall will start again. Part A of Curve 4 shows that the surface tension was constant for more than an hour after the solution was poured in the capillarimeter. A decided drop took place, however, during the next eleven hours. A gentle agitation then caused the surface tension to return to its maximum value. Part B shows that the drop started at once after this gentle agitation. After reaching a low value the solution was vigorously agitated, resulting again the maximum value. The two hour period which elapsed, after this more violent agitation, before the fall started is shown in part C. The effects of two more gentle agitations and a second violent agitation are shown in parts D, E, and F.

Periods of inactivity of this sort have been noticed by us in work with solutions of other organic substances. J. M. Johlin observed similar periods of inactivity with dilute solutions of sodium oleate and casein, but makes no

attempt to explain them. We recognize that our suggestion that a metastable state is established is inadequate as an explanation, but feel that it contains a hint worth following.

The suggestions we made in connection with our experiments with solutions of glycerol, are at least plausible here also. Let us assume that the lower surface tension values are due to the adsorption of the solute on the glass walls of the capillary and at the liquid-vapor interface of the meniscus. The gentle agitation serves to remix the solution in the meniscus but does not remove the adsorbed layer from the walls. The solution, now uniform, shows its appropriate surface tension, but adsorption in the meniscus starts at once and the surface tension soon falls. A vigorous agitation, on the other hand, not only remixes the solution in the meniscus but also removes the adsorbed layer from the walls. The fall is delayed by this treatment; perhaps a layer of the solute has to be adsorbed on the walls before the increase in concentration in the surface layer of the meniscus starts, or becomes effective in lowering the surface tension.

We observed a rather curious and interesting phenomenon with these solutions not shown in the curves. If, when the surface tension is at a minimum value, the meniscus is drawn down still farther in the capillary and then is allowed to ascend of its own accord, it rapidly comes back to the point at which it stood before it was lowered. No matter how far it is lowered, or how many times, the meniscus flies back to its original position as though drawn by a rubber band. If, however, the meniscus is gently forced a few millimeters above, not necessarily to its maximum point, and then lowered, it will fly up to the point to which it was forced. It does not hesitate as it passes its old minimum value. If the meniscus is forced above its maximum, or original value, it will fall to this point; if it is then drawn below it will rise to the same point.

A plausible explanation for this behavior is as follows. Water evaporating from the walls left wet by the descending column leaves a thin invisible layer of the solute. When the meniscus is drawn down and is allowed to fly back it will stop when it reaches the thin layer of the solute, because if it went further, it would dissolve the solute, become more concentrated and have a lower surface tension. When the meniscus is forced up a short distance it dissolves the solute from the walls and then will, if lowered, come back to the new and higher level where the walls are still coated with the comparatively dry solute.

Another of the puzzling phenomena which we noted in these experiments with resorcinol is the fact that a slight rise often takes place after a rather rapid fall. The rise, never amounting to more than a fraction of a dyne, is not always the same, nor does it always occur at the same point of the curve. After this rise has taken place the surface tension proceeds to fall slowly to some point below that at which it started to rise. Irregular results similar to these were noted by J. M. Johlin in work with solutions of gelatin. In the light of recent work of du Noüy, one may be justified in ascribing this slight rise, followed by a fall slower than the initial fall, to some sort of molecular orienta-

tion or rearrangement taking place in the surface layer. There is, however, no experimental proof that such an orientation would result in such a rise. We cannot ignore, on the other hand, a peculiar phenomenon which happens as consistently as this one has happened.

Solutions of Pyrogallol. The pyrogallol which we used was a standard C.P. grade.

At A and B vigorously agitated throughout the capillary. At C slightly agitated below the resting point. At D slightly agitated throughout the capillary. At E slightly agitated below the resting point. At F vigorously agitated throughout the capillary. At G vigorously agitated below the resting point. At H slightly agitated throughout the capillary. At I vigorously agitated below the resting point. At J slightly agitated throughout the capillary. At K vigorously agitated below the resting point. At L vigorously agitated throughout the capillary. At M vigorously agitated below the resting point. At N vigorously agitated throughout the capillary. At O slightly agitated below the resting point.

These results are of the same nature as those which we obtained with solutions of resorcinol and are readily explained by the same reasoning. A vigorous agitation throughout the tube is often followed by a period of inactivity before the fall starts. This is shown by the portions of the curve following the points B, F, and N. The duration of this period is not always the same, in fact, the fall sometimes starts almost at once but proceeds slowly as is shown by the curves following the points A and L. One reason for this difference undoubtedly lies in the fact that the agitation is not always of the same degree of violence; it is also probable that the adsorption on the walls has progressed to a greater extent in some cases than in others. According to our hypothesis

the vigorous agitation not only remixes the solution in the capillary but also removes the adsorbed layer from the walls. A gentle agitation, however, serves only to mix the liquid in the surface layer with the rest of the solution, and does not remove the layer from the walls. Such gentle agitation is invariably followed by a comparatively rapid fall as is shown by the steep portions of the curve following D, H, and J.

The fact that agitation, either gentle or vigorous, below the resting point of the meniscus in each case caused the liquid to come to rest at a point lower than that at which it had stood before is evident, (see points C, E, G, I, K, M, and O). This indicates that here has been lag in the fall, the decrease had not been quite keeping up with the adsorption of the solute. The agitation upset a metastable state and then the system moved to the proper point, as determined by the amount of adsorption which had taken place.

These experiments, showing the effect of agitation on the surface tension changes of solutions of glycerol, resorcinol, and pyrogallol, are, we feel, of significance. They are the most direct experimental evidence which has yet been offered in support of the theory that falling surface tensions can be caused by the adsorption of the organic solute at the liquid-glass interface as well as the liquid-vapor interface.

Solutions of Phenol. Variations in surface tension which are not readily accounted for on the basis of the theory which we have just outlined have been observed to take place with solutions of phenol. Many experiments were carried out with this substance in a vain attempt to reproduce conditions so that the same type of variation could be consistently obtained. The following curves illustrate the kind of irregularities which occur.

The fall in surface tension usually started at once, either with a new solution or with a freshly agitated one, although there was sometimes a short period of inactivity. The initial maximum values were reproducible without difficulty. In most of the experiments it was noted that, after a fall had taken place, the meniscus would slowly rise again to some point midway between the minimum and maximum values. This reversal would sometimes occur

within an hour after the start of an experiment, while in other cases several hours would pass without interruption of the steady downward trend. This rise is probably caused by the same phenomenon as that which was involved in experiments with resorcinol, and is perhaps of the same nature as that which caused the irregular results noted by J. M. Johlin with solutions of gelatin, and du Noüy with solutions of sodium oleate. At present we cannot account for this rise, and are unable to regulate the conditions which determine it.

Solutions of Other Substances. Surface tensions decreasing with time have also been noted and studied with solutions of oxalic, propionic, and succinic acids. As these studies discovered nothing beyond what we have described, details are omitted. Some other substances, which from analogy one would expect to form solutions showing decreasing surface tensions with time, as acetic acid, or sodium acetate, have very little effect on the surface tension of water.

Solutions showing an Increasing Surface Tension with Time

In preparing capillarmeters for experiments, after the cleaning and washing, they were dried by drawing dry air through them. In the preliminary stages of our work we employed an ordinary drying train, containing calcium chloride, soda lime, and cotton, and after passing through this, the air passed

through a rubber tube before entering the capillarimeter. We became suspicious of this tube and felt that it was at least possible that minute solid particles, or gaseous emanations from the rubber, might contaminate the walls of our instrument. In order to determine what effects such contaminations might have, we attached a rubber tube which had been in use for some time on a Bunsen burner. This was exceedingly effective and surface tension values obtained after this treatment were most erratic. We substituted glass tubes and ground-glass joints in such a manner that the air came in contact with no rubber before entering the instrument, thus effectually eliminating trouble from this source.

But evidently something from the rubber was one of the hitherto overlooked sources of error for which we were searching. We decided to investigate this. Accordingly we passed illuminating gas through a clean capillarimeter for two or three minutes, washed the capillarimeter twice with water, and then determined the surface tension of water. We were surprised to observe an increase with the passage of time. In one hundred and fifteen minutes the surface tension increased from 70.7 dynes to 72.2 dynes.

Illuminating gas is of indefinite composition, accordingly we turned to pure gases. We passed hydrogen, nitrogen, oxygen, carbon dioxide, sulfur dioxide, and methane through clean capillarimeters, determining the surface tension of water in them after each treatment. The values obtained differed but little from the surface tension of pure water. In no case could we detect an indication of an increase in surface tension with the passage of time.

But these gases by no means exhaust the list of substances present in illuminating gas. Something from the gas must have clung to the walls. It might act in either of two ways. First, soiling the walls it would cause us to get too low a result, then, dissolving in the water the walls would become clean, and we should get the higher, correct value. Or, second, this foreign material might dissolve in the water at once and produce a lowering of its surface tension, and then it might evaporate from the meniscus until pure water was left, with its corresponding value.

Solutions of Amyl Acetate. Following this idea we turned to volatile substances which might be expected to evaporate from the surface of a water solution. Naturally we selected definite chemical compounds. Our first qualitative experiments were made with solutions of amyl acetate. We added one drop of amyl acetate to 100 cc. of water and put the solution in a capillarimeter, and were gratified to observe an increase in surface tension from 62.6 dynes to 69.6 dynes in half an hour. In observing the changing surface tension we were guided by our previous experience with falling surface tensions and so refrained from agitating the solution before each reading; we merely watched it climb.

This decided increase led us to study in a semi-quantitative manner the solutions of several different substances of the same type. The organic liquids used were purchased from Eastman Kodak Co., and unless so stated were

not purified further by us. Conductivity water was used in making up the solutions. These studies were only preliminary in nature, and the results should be considered as relative only.

Solutions of ethyl acetate, propyl butyrate, and butyl acetate show the phenomenon. A small increase in surface tension with time was noted with a dilute solution (about 2%) of ethyl alcohol. Aqueous solutions of amyl alco-

hol, propyl alcohol, and iso-propyl alcohol, displayed more pronounced increases with time. Ethylene dichloride and acetone when dissolved in water also gave definite increases in surface tension as time elapsed.

In general, the greater the initial lowering of surface tension caused by the solute the greater and more rapid is the increase following. With the substances we used, the higher the molecular weights the greater the effects on the surface tension of water. The solubility in water, however, decreases with increasing molecular weight and this fact limits the number of substances which we can use advantageously.

Solutions of Propyl Formate. A fifth molar solution of propyl formate showed an increase in surface tension from 47.8 dynes to 62.8 dynes in two hours. Agitation caused the surface tension to return to its minimum value from which a second increase took place.

Solutions of Methyl Acetate. A molar solution of methyl acetate was used in several experiments intended as a more careful study of the rate of increase, and also of the effect of agitation in causing the drop from a maximum to a minimum surface tension. The results of a typical experiment with this solution are shown in Curve 9.

During the first two hundred and seventy-six minutes there was no agitation, and the surface tension increased from 47.5 dynes to 60.6 dynes. Then

the surface was agitated, by drawing it slowly up and down the tube once, after which a reading was taken. Then the liquid was again drawn up and down once, and a second reading was taken. This was repeated six times.

Manifestly the effect of agitation is cumulative and would finally result in a value practically the same as the initial reading.

Solutions of Propyl Acetate and Temperature Effects. Numerous experiments were carried out with solutions of this material in an attempt to find out the effect of different temperatures on the rate of the surface tension change.

The initial readings show, as was to be expected, the lowest surface tension at the highest temperature and the highest surface tension at the lowest temperature. Whatever the change which produces the increasing surface tension, it proceeds faster the higher the temperature. It looks as though we had reached the equilibrium condition at 40° after about 140 minutes. But the surface tensions at the lower temperatures are still ascending. The 30° curve crosses the 40° curve after 185 minutes and the 20° curve is gradually approaching that for 30°. We believe it will ultimately cross it. In short we feel justified by experiments in believing that the final equilibrium surface tension will be higher, the lower the temperature.

Quantitative Study. We felt that this phenomenon of rising surface tension was worth investigating quantitatively. It was necessary to choose one substance with which to work. It seemed desirable that the substance should show the phenomenon in as marked a degree as possible, that is, its solutions should have a surface tension much different from that of the solvent, water. It should be soluble enough to permit the study of a wide range of concentra-

tions; it should have a much higher vapor pressure than water, and not be readily hydrolyzed. Ethyl acetate was chosen as the solute best fulfilling these specifications.

Purification. Our stock ethyl acetate from the U. S. Industrial Chemical Co., was fractionated and that portion distilling over between 76.9° and 77.2° was reserved for further fractionation. After drying over phosphorous pentoxide for several hours this fraction was poured off and redistilled. A large amount which came over at nearly constant temperature was collected and preserved in a glass-stoppered bottle. The boiling point corrected to 760 mm. pressure varied from 77.11° to 77.20° . For this correction use was made of the dt/dp values obtained by J. Wade and R. W. Merriman.¹ The boiling point which they observed for pure ethyl acetate at 760 mm. was 77.15° . We found the density of our ester to be .9003 at 20° , which compares favorably with the density of .9005 recorded by Wade and Merriman for the same temperature.

A contraction in volume occurs when ethyl acetate dissolves in water and this contraction must be taken into account in making up solutions of definite concentration. We spent more time than we should have over this, actually determining experimentally this contraction. The details would not be of any general interest. We satisfied ourselves that making up solutions by diluting measured volumes of ester to calculated volumes of solution did not introduce a perceptible error in our results.

If the density of the vapor phase, air saturated with water and ethyl acetate, is much different from air saturated with water only, an error is introduced. (See formula ($\gamma = \frac{1}{2} \text{ hrg } (D - d)$). The density of air at 20° saturated with water vapor is 0.0012. We made numerous determinations experimentally of the density of the vapor phase, air saturated with water and ethyl acetate over an M/2 ethyl acetate solution. The average of our results was, 0.001256. Error resulting from neglect of this correction was clearly negligible and so we used, $d = 0.0012$ throughout.

Ethyl Acetate. The following curves obtained with half molar ethyl acetate to show the type of rise we obtained and the limits within which one may expect to reproduce results.

Agitation, by means of blowing and drawing, after each maximum value, caused the surface tension to return nearly to its original minimum value from which the usual rise again took place.

Curves 13 and 14 were obtained with both arms of the capillarmeter open to the air, while for curve 15 loose caps were hung over the open ends. The fact that these three curves are nearly identical is explained by the fact that the caps fitted loosely, allowing vapor to diffuse out as rapidly as it diffused up through the capillary.

We next joined the two arms of the capillarmeter with a piece of tightly-fitting, black gum, rubber tubing, and carried out the experiment resulting in curve 16. We thought that under these conditions the vapor phase would soon become saturated with the vapors of water and of ethyl acetate. An

¹ J. Chem. Soc., 101, 2438 (1912).

equilibrium would thus be reached at the meniscus, and there would be no further concentration change in this and consequently a constant surface tension would be obtained. The curves show that the presence of the rubber tubing made no noticeable difference. The rise proceeded at the same rate as before. The experiment was repeated many times but always with the same result. Even after being thus closed in the capillarmeter for several days the

solution would show the usual rise from the minimum, obtained after an agitation, to a maximum value. This almost caused us to abandon the theory that the rise was due to evaporation of the ethyl acetate from the meniscus faster than it was replaced by diffusion from the interior.

Fortunately it occurred to us that perhaps the ethyl acetate was dissolving in the rubber, thus preventing the establishment of equilibrium at the meniscus.

Two pieces of black gum rubber tubing about three centimeters long, equipped with platinum hooks, were carefully dried and weighed. One of them was then suspended from a glass rod in a flask above distilled water, as shown in Fig. 5. The second piece was suspended above a half molar solution of ethyl acetate in a similar flask. After being in contact with the vapors in the flasks for some hours, the rubber tubes were again weighed. The original weight of the rubber tube which was suspended above water was 1.5420 gms. After eight hours and fifty-three minutes of contact with water vapor it weighed 1.5500 gms. The original weight of the rubber tube which was suspended above M/2 ethyl acetate was 1.5950 gms. After eight hours and fifty-three minutes of contact with the vapor above the solution it weighed 1.7500 gms., a gain of .1550 gms.

After twenty-three hours and thirty minutes the tube above the water showed a gain of .0165 gms., while the tube above the solution of ester for the same length of time, showed a gain of .1850 gms.

A similar experiment carried out with water and an aqueous solution of propyl acetate gave very similar results. Evidently rubber will take up large amounts of ester vapors. After being exposed to the air for several hours the

tubes again showed their original weights. This explains the fact that the closing of the capillarmeter with a rubber tube in experiment 16, caused no change in the rate of increase of surface tension. The tube did not close the system and prevent evaporation. It might as well not have been there.

Vapor lost by Diffusion. In order to find out whether or not the amount of vapor absorbed by the rubber tube was comparable with the amount which would ordinarily evaporate and diffuse out of the capillary tube of a capillarmeter, the following experiment was carried out. A capillary tube with a bulb at one end, as shown in Fig. 6, was filled with half molar ethyl acetate solution to within about 3.3 cm. of the top. Sixteen hours were allowed for the drainage and drying of the capillary walls above the meniscus. Owing to the short length of the tube above the meniscus, more ethyl acetate should evaporate and diffuse from this tube than from the capillary of any capillarmeter used. After the sixteen hour period the meniscus was 3.50 cm. from the top. The instrument was then weighed after different time intervals with the following results.

Loss after 10 hours	.0002 gms.
" " 15 "	.0005 "
" " 48 "	.0015 "
" " 72 "	.0027 "

After seventy-two hours the meniscus was 4.06 cm. from the top, a fall of about .56 cm.

This experiment proves that the amount of ethyl acetate and water which will evaporate and diffuse from a capillary, of the size used in our capillarmeters, is much less than the amount which the rubber tube is capable of absorbing in the same time.

Closed Capillarmeter. In order to close completely the capillarmeter and obtain saturation of the vapor and equilibrium at the meniscus, we made use of an instrument constructed as shown in Fig. 4. With the stopper out the system was open; with it in, it was truly closed.

The following curve is representative of the many which we obtained with solutions of different esters and alcohols in capillarmeters of this type.

In another experiment carried out in the same capillarmeter at 20° with half-molar ethyl acetate, the initial surface tension was 42.3 dynes. After one and a half hours with the system open the value increased to 54.0 dynes, the system was then closed and after another hour and a half the surface tension had decreased to 42.4 dynes. The system was again left open for one and a half hours, and the surface tension increased to 54.4 dynes. The glass stopper was then inserted, and twelve hours later the surface tension was 40.2 dynes.

The fact, that the surface tension stopped increasing and started to decrease as soon as the system was closed with a glass stopper, must be due to the gradually increasing concentration of the ester in the vapor phase. It was often observed that the value obtained for the surface tension of a solution, after the capillarmeter had been closed for some time, was lower than the value shown by the solution immediately after being poured into the capillarmeter. This is probably due to the difficulty of obtaining a reading of the position of the meniscus, before a slight rise has taken place.

FIG. 5

FIG. 6

Experiments in Side Arm Capillarimeter. Convincing evidence that the extremely small amount of ethyl acetate which does evaporate and diffuse through the capillary in one of our instruments is sufficient to cause the observed change in surface tension is given by the following experiment. A capillarimeter was constructed with a side arm attached above the capillary tube, as shown in Fig. 3. Pure water was placed in the main part of the in-

strument and its capillary rise noted. Half molar ethyl acetate was then placed in the side arm and the following curve was obtained.

The fall is obviously due to the evaporation of the ethyl acetate from the side arm, diffusion through the capillary and its solution in the surface. After 30 minutes, when the value 56.6 dynes had been reached, the solution in the capillary was violently agitated with the result that the surface tension rose to 70.8 dynes. This was evidently because the comparatively concentrated layer in the meniscus got stirred into the body of the liquid. At 70 minutes we removed the ethyl acetate solution from the side arm and agitated the solution as before, we immediately got a value of 72.1 dynes which rose to 72.6 in 24 hours.

We have shown that the actual amount of ethyl acetate which would evaporate and diffuse through our capillary tubes is very small, less than .0002 gms. in ten hours or about .00001 gm. in thirty minutes in a tube the length of this one. Yet this extremely small amount was sufficient to cause a drop in surface tension of sixteen dynes. This is a convenient and striking way to demonstrate the known fact that minute traces of some substances produce marked effects on surface tension.

Rise after Minimum Value. In many of the experiments carried out as described for Curve 18, it was observed that after the minimum value was reached a slight increase would take place. More careful investigation showed that this increase always took place if the experiment was continued long enough, providing that the liquid in the side arm was a solution of the ester and not the pure ester. The magnitude of the changes involved is shown in the following characteristic curve.

This behavior is readily explained. The meniscus is gaining ethyl acetate due to evaporation from the side arm and is losing it as it diffuses downward into the liquid. Simultaneously the evaporation in the side arm is diminishing due to the the diminishing concentration in that surface. These effects all balance at the minimum apparent on the curve at 60 minutes. After this the meniscus loses by diffusion faster than it gains from the side arm. But when we renewed the surface in the side arm by agitation, the curve took a downward trend again.

Diffusion through Gases. Measurements such as these could readily be developed into a convenient method of studying the rates of diffusion through gases in capillary tubes. They could also be used to measure the rates of diffusion from the surface into the body of the liquid.

Diffusion through Liquid. In an ordinary open capillarimeter (Fig. 2) we placed some half-molar ethyl acetate. We then carefully inserted some pure water in the capillary tube, enough to cover the solution meniscus with a water layer about one centimeter thick. The only way in which the ester can affect the surface tension of such a system is by diffusion up through the water to the meniscus. Of course a little of the solution is likely to stick to the walls of the tube and thus contaminate the water as it is poured in. With careful manipulation, however, such effects are very small. Several experiments of this sort, at 20°, did not show any change in several hours. In order to hasten diffusion we then carried out experiments at 40°. The following results are typical.

Time elapsed.	Surface tension
0 minutes	68.8 dynes
47 "	68.4 "
215 "	68.5 "
1080 "	68.7 "
solution agitated	52.3 "

The surface tension remains nearly that for pure water, not enough ester molecules diffusing through the water in over eighteen hours to cause any lowering. After this interval the solution was agitated by drawing it down out of the capillary several times. Enough ester was thus mixed with the water to cause a large lowering in the surface tension. Evidently diffusion through the liquid phase must be very slow. This method is capable of development and may be of some practical value.

Incidental Observations

It was our original purpose to discover, investigate and report as many sources of error as possible connected with the measurement of surface tension by the capillary tube method. We shall, therefore, now present a few incidental observations which were made.

Drops. It often happens that a drop (ring of liquid) forms at some distance above the meniscus. Following is a description of one instance. It occurred when working with half molar propyl acetate. In the initial reading the top of the meniscus, A (Fig. 7) stood at 13.000, while the bottom of the

drop, B, stood at 13.200 on our cathetometer scale. Twelve minutes later the meniscus A had ascended to A', 13.180, while the drop had remained stationary. Immediately after taking this reading the drop B suddenly disappeared and at once the meniscus rose to A'', 13.260, slightly above the place where the top of the drop had been. The drop is formed by drainage of the solution left on the walls after wetting, and just as in the well-known phenomenon of "tears on strong wine," it rapidly becomes more nearly pure water by the evaporation of the ester. Evaporation is going on at the surface of the meniscus also, and, as a result, the meniscus rises until it approaches near enough to the drop to draw it to itself, or to be drawn up by the drop, resulting in a sudden increase in surface tension due to the more nearly pure water of which the drop is composed.

FIG. 7

The same phenomenon has often been noted in a slightly different form. The whole length of capillary having been wet by the solution, a drop was seen to form as at A in Fig. 8. The tube being a rather wide one the drop began to fall slowly. The fall was followed by the telescope and it was noted that when it was within a few millimeters of the meniscus it suddenly disappeared

FIG. 8

downward into the meniscus, which in turn, ascended quickly to a new height. Not nearly enough liquid descended in the drop to account for the rise noted. During its gradual fall the drop had become more nearly pure water, due to the evaporation of the ester, and when near enough to the meniscus to be pulled into it, it simply exerted its proper surface tension.

It is probable that small drops are formed on the walls of the tube above the meniscus fairly often. They may be too small to be seen, but large enough to be the cause of the rapid increases sometimes noted, and unaccounted for in any other way.

Throbbing. Many of our experiments have failed to give us a smooth, uniform rise. During its ascent, the meniscus would often pause, fall rapidly and then rise slowly as before. When a point, slightly higher than the one from which the fall had taken place before, was attained, another drop followed by another rise, took place. This phenomenon was often repeated many times in the course of an experiment. The range of these pulsations varied, from a small fraction of a dyne in some instances to four or five dynes in other. We found it convenient to refer to this behavior as a "throbbing."

The frequency of this throbbing, as well as the range, varied a good deal. Sometimes several minutes would elapse between throbs, while at other times they would follow each other in rapid succession. Constant vigilance was the price of a numerical record of this phenomenon. Several experiments were carried out, during which, careful watch was kept on the meniscus, a reading being taken every time that it changed the direction of its motion. Several of these records will be given to show the extreme lack of regularity in these variations.

This throbbing was evident in probably thirty per cent of the experiments which involved an increasing surface tension. It seems much more apt to occur if the increase starts out rapidly than if it starts slowly. It very seldom occurs in an experiment involving a decreasing surface tension, although we have noted it in a few such experiments.

As a possible explanation we offer the following suggestion. We have learned by experience that it is exceedingly difficult to make the surface of a capillary tube (or any other surface) strictly clean, and yet more difficult to keep it so, even for a short time. It is perfectly possible that, in spite of all our precautions our tubes were not entirely clean. Then as the meniscus rises it will dissolve contamination until the surface acquires a lower surface tension, compelling a fall. Its subsequent ascension is not hindered in the interval through which it dropped for the walls were cleaned by the motion of the liquid. Therefore the meniscus rises rapidly and uniformly through the distance it fell, and rises higher until it gathers up more contamination; enough to produce the next fall.

Again the phenomenon may be due to molecular rearrangements in the surface film. This idea of definite molecular orientations is truly fascinating. If we give free rein to our imagination, as seems to be the fashion just now, we may conceive that the molecules of ethyl acetate in a dilute solution travel around in schools, or molecular swarms, and when such a swarm arrives at the meniscus there is a corresponding drop in the surface tension. This idea is not without support. For instance, J. M. Johlin¹ makes the statement: "Evidence of rearrangements at the surface is indicated by the frequent throbbing or pulsating of the meniscus, without necessarily resulting in any immediate change in surface tension—a fact invariably observed in all experiments with a wider capillary."

We are inclined to be conservative and, while admitting the possibility of such an explanation, prefer not to commit ourselves at present.

Effect of Size and Shape of Capillarimeters. It became evident to us that, although the initial, minimum values were easily reproducible, the rate of increase of surface tension varied with different capillarimeters. With instruments of nearly the same shape and dimensions the differences in rate were not great. But with capillarimeters of radically different type greater variation is evident. For example, the rise noted in capillary D when used in the form illustrated in Fig. 2 was more rapid and a higher maximum was reached than when the tube was used in the form illustrated by Fig. 4.

This variation is adequately explained on the basis of the evaporation theory. The air and vapor in the tube above the meniscus is stagnant, that is, it is not readily removed by external air currents. It is natural to suppose that it is more stagnant in an instrument of the type shown by Fig. 4 than in the kind illustrated by Fig. 2, for in the former case there is only one opening to the atmosphere while in the latter case there are two.

¹ J. Phys. Chem., 29, 282 (1925).

It is more difficult, however, to account for the fact that in capillarimeters which are alike except for the diameter of the capillary, the phenomenon proceeds more rapidly in the capillary of the smaller diameter. If simple diffusion of gases was the controlling factor in the velocity of the change we would expect it to be greater in the larger tube. At present we have no plausible explanation to offer.

Concentration in the Surface. We carried out experiments in which we determined the true surface tension of ethyl acetate solutions of different concentrations. In obtaining the true surface tensions of these solutions two methods are available. Experience has shown us that the best method is to use a closed capillarimeter and to allow sufficient time for the atmosphere to become saturated with the vapor of the solution. The second method is simply to note the initial minimum value before any change with time has taken place. This method usually gives values slightly higher than the first, due to the difficulty of determining the initial point of a slowly moving meniscus. With careful but rapid manipulation, however, it is possible to check, very closely, results by the two methods. In the following table the method or methods used, are stated in each case. Several different capillarimeters were used in these experiments, no difficulty being experienced in checking minimum values with the different instruments. Temperature $20.0^{\circ} \pm 0.1^{\circ}$.

Concentration Molar		Surface tension	Method	Lowering from water value
M/1.5	.6666	37.6 dynes	open tube	35.1
M/2	.5000	42.2 "	both methods	30.5
M/3	.3333	47.9 "	both methods	24.8
M/4	.2500	51.5 "	both methods	21.2

M/7	.1428	57.4 "	open tube	15.3
M/8	.1250	58.1 "	both methods	14.6
M/9	.1111	59.3 "	closed tube	13.4
M/10	.1000	59.9 "	open tube	12.8
M/12	.0833	61.9 "	open tube	10.8
M/14	.0713	63.5 "	open tube	9.2
M/15	.0666	63.5 "	open tube	9.2
M/16	.0625	64.0 "	both methods	8.7
M/18	.0555	64.7 "	both methods	8.0
M/22	.0454	66.1 "	open tube	6.6
M/24	.0416	65.9 "	closed tube	6.8
M/33	.0333	67.3 "	open tube	5.4
M/36	.0277	66.9 "	closed tube	5.8
M/40	.0250	67.5 "	both methods	5.2

Plotting these results we obtain Curve 25. We can read off from this curve directly the concentration of the solution which must correspond to any particular surface tension. It would be going too far to make the simple assumption that the concentration at the meniscus is the same as in the interior of the

liquid under these conditions. But it may be. Whatever the conditions actually are we have here an interesting relationship which will be of help in elucidating them.

H. Freundlich¹ gives an equation connecting surface tension lowering with concentration.

$$\Delta = \frac{\gamma_m - \gamma_1}{\gamma_m} = Kc^{1/n}$$

Where Δ is the lowering of surface tension to be expected for any concentration c ; γ_m is the surface tension of the pure solvent; γ_1 the surface tension of the solution; K and $1/n$ are constants. That our experiments agree essentially with the formula is shown by the nearly straight line obtained when the logarithm of the concentration is plotted against the logarithm of the lowering. Curve 25a.

Rate of Increase. We have advanced the theory that increase of surface tension with time is due to evaporation of solute from the surface faster than it is replaced by diffusion from the body of the solution. Certain deductions from this theory are possible. When an apparent maximum surface tension is reached the rate at which the surface is losing solute by evaporation is equal to the rate at which it is gaining solute by diffusion. But this must be only an apparent maximum for, given time enough, practically all solute will reach the surface and will evaporate. The true maximum must always be the surface tension of pure water. Replenishment of the surface must be directly proportional to the concentration from which diffusion takes place. Consequently the increase in surface tension should be most rapid at the beginning and should fall off with time. This deduction has been abundantly verified.

It follows that when a solution of greater concentration, say $M/2$, has reached a point where it shows a surface tension corresponding to a lower concentration, say $M/5$, the adjacent layers have been impoverished and diffusion must proceed through a greater distance. Therefore the rate at which the surface tension of this solution increases should be less than the initial increase shown by an $M/5$ solution. We put this deduction to the test of experiment.

Our deduction is well justified. At the expiration of 60 minutes the $M/2$ curve showed the surface tension corresponding to an $M/5$ solution. Its slope at this time is obviously less than the initial slope of the $M/5$ curve. At the expiration of 60 minutes the $M/5$ curve showed a surface tension corresponding to an $M/10$ solution and its slope is less than the initial slope of the $M/10$ curve, and so on.

Hydrolysis. The substances with which we have worked hydrolyze, and if this occurs with sufficient rapidity our results give the surface tensions, not of solutions of our initial substances, but of the products of the hydrolysis.

We investigated this matter and found that the rates of hydrolysis varied greatly with different esters. In general, esters of lower molecular weight

¹ "Kapillarchemie," 90 (1922).

hydrolyze faster than those of higher. For example, a solution of methyl acetate hydrolyzes more rapidly than a solution of ethyl acetate of the same molecular concentration.

We proved by experiment that a solution of ethyl acetate in water hydrolyzes very slowly, too slowly to invalidate any of the results we have reported.

Two half molar solutions of ethyl acetate were made up and kept in glass stoppered flasks. These flasks were suspended in a constant temperature bath at $20.0^\circ \pm .5^\circ$. Samples were removed from time to time and titrated with standard barium hydroxide, using phenolphthalein as the indicator.

Solution 1			Solution 2		
Time elapsed		Per cent hydrolyzed	Time elapsed		Per cent hydrolyzed
0	Hours	.026	0	Hours	.026
12	"	.026	23.5	"	.033
48	"	.040	71	"	.13
136	"	.16	126	"	.16
181	"	.23	179.5	"	.26
252	"	.43	314	"	.83
496.5	"	1.36	483	"	1.85
665	"	2.43	657	"	3.33
827	"	4.00	4689	"	86.0

During the last five months solution 2 was kept at room temperature, several degrees above the temperature of the first part of the experiment.

We ran surface tension determinations on this 86% hydrolyzed solution and found an initial value of 55.5 dynes which increased to 58.2 dynes in 13 hours. Thus, when the solution is hydrolyzed, the minimum value is higher and the maximum value is lower than when it is fresh and not hydrolyzed.

This experiment, and several others, showed us that surface tension of solutions of esters increases as hydrolysis progresses. It is therefore possible to plot a curve, surface tension against degree of hydrolysis, from which it

will be possible to read directly the degree of hydrolysis corresponding to any particular surface tension. Of course it will be necessary in making or using such a curve to deal only with the minimum or true surface tension of any particular solution. As has been explained, this is best obtained by the use of a closed capillarmeter.

We obtained data for such a curve by making measurements upon an M/2 ethyl acetate solution which we caused to hydrolyze at a convenient rate by warming. Care was taken to allow no change in concentration due to evaporation. The degree of hydrolysis was determined by the usual barium hydroxide titration, carried out simultaneously with the measurement of surface tension. The value corresponding to a completely hydrolyzed solution was obtained by making up a solution of ethyl alcohol and acetic acid in the proper proportion to form a 100% hydrolyzed solution. Titration showed that this solution corresponded to 99.8% hydrolysis.

This is capable of being developed into a method for measuring the degree of hydrolysis of solutions of esters. Experiment has shown us that the surface tension of solutions of substances such as ethyl acetate may be readily determined to within 0.4%, with ordinary instruments and technique. We ob-

served that as a half molar solution of ethyl acetate changed in hydrolysis from 0% to 100% the surface tension underwent a total increase of 16.5 dynes. Our measure of the hydrolysis by the surface tension method was then accurate to within approximately $\pm 2.4\%$. ($.4/16.5 \times 100 = 2.4\%$)

The rate of any chemical reaction, resulting in a sufficiently large change in the surface tension, can be followed by this method.

Summary

(1) The decrease of surface tension with time, of solutions of sodium oleate, sodium glycocholate, and glycerol, as observed by earlier workers, has been confirmed. We have demonstrated that the same phenomenon occurs with solutions of other substances such as, phenol, resorcinol, pyrogallol, propionic acid, valeric acid and succinic acid.

(2) We have obtained experimental evidence in support of the theory that this phenomenon is caused by the adsorption of the organic solute at the glass-solution interface as well as at the vapor-solution interface.

(3) Contrary to the opinion of du Noüy we have shown that the phenomenon may be observed and adequately studied by the capillary rise method. Several of the facts which we have found could hardly be observed in any dynamic method of measuring surface tension.

(4) We have observed, perhaps for the first time, that solutions of certain esters and alcohols show an increase in surface tension with time. With these solutions, after a rise to a maximum, the fresh surface formed by agitation displays the original minimum value, from which another rise will start at once. A careful study of such changes as they occur with solutions of ethyl acetate has been made.

(5) We have offered a plausible explanation of the phenomenon, and have obtained much experimental evidence in its support.

(6) We have demonstrated the necessity of using a closed capillarimeter in measuring the surface tensions of numerous solutions and have shown that rubber connections cannot be used.

(7) We have measured the surprisingly small quantity of solute necessary to produce extensive lowering of the surface tension in a new way, one of which may have some applications.

(8) We have suggested a method for estimating the rates of diffusion to and from surfaces, and for estimating the concentration at the surface of a meniscus.

(9) We have devised a method for estimating the degree of hydrolysis of a solution of an ester.

(10) In conclusion; we believe we have contributed in some slight measure, at least, to our knowledge of the possibilities and limitations of the capillary rise method of measuring surface tension.

THE CRYSTAL STRUCTURE OF POTASSIUM

BY E. POSNJAK

Introduction

Among the large number of substances which have at one time or another been X-rayed, the record for potassium is, in a way, a singular one. According to the record no regular diffraction of X-rays, but only a so-called general scattering is obtained at room temperature by the usual powder method. The first to investigate the crystal structure of the alkali metals was A. W. Hull.¹ He reports encountering considerable difficulties in obtaining X-ray diffractions from sodium and lithium and the failure to obtain any from potassium. The observation that no diffraction was obtained from samples made from freshly melted sodium and lithium and that even samples made from old stock produced a large amount of continuous scattering led him to believe that sodium and lithium were only partly crystalline and that the potassium must be completely amorphous. Later McKeehan² reinvestigated potassium. He found that if the potassium is cooled to -150° , weak reflections as from large crystals are obtained; however, he says that this "crystalline structure does not persist when the temperature is allowed to rise again to about 20° ."

The conclusion derived from X-ray experiments, that potassium must be amorphous at room temperature, is very surprising, as the fractured surface of potassium shows brilliant facets and well-defined crystals have been grown even from the molten metal³; and further, of course, because potassium has a definite and sharp melting and freezing point. It is not quite conceivable that an amorphous substance could possess such properties, and R. W. G. Wyckoff⁴ in discussing this case in his book on "The Structure of Crystals" tries to explain these conflicting facts by the assumption, not that potassium is an amorphous substance, but that the amplitudes of the thermal vibrations of potassium atoms at room temperature are so great as to "obliterate the crystalline diffraction maxima." We do not need, however, to go into the details of this discussion, as it will be shown below that the assumption is unnecessary. The reason for mentioning it is chiefly to call attention to the danger of drawing definite conclusions and of putting too much reliance on a few negative results of X-ray experimentation.

The present investigation grew out of experiments on non-crystalline substances, of which potassium was supposed to be one. Contrary to such statements, every sample of potassium that was X-rayed in this investigation

⁴ Wyckoff: "The Structure of Crystals," 372-373 (1924).

showed normal diffraction effects. In view of this, and for comparison results, a few preparations of sodium and one of lithium were made and X-rayed. These substances also in each case gave definite diffraction effects, which were in good agreement with previous determinations of their crystal structure, and only a short statement concerning these experiments will therefore be given below.

Experimental Part

Material and preparation of samples. Metallic potassium from two different sources was used in this work. The stock of one had been in this Laboratory for more than ten or fifteen years and had been originally obtained from the firm of Eimer and Amend. The other was specially obtained for the present experiments from the J. T. Baker Chemical Company (lot NS 52827). Their melting and their freezing points were determined approximately and found to lie close to 62° , which is very near the accepted value for potassium.

Owing to the original interest in potassium as a supposedly non-crystalline substance, Hull's observation, that the freshly melted or distilled alkali metals appeared to be in an amorphous condition, served to indicate the way of preparing such samples. After some trials, it was found that a thin capillary tube could readily be filled with potassium when the metal was in the molten condition. The following simple procedure was used. A Pyrex tube about 30 cm long and about 2 cm in diameter was sealed off at one end, and a side tube with a good stopcock was sealed on near the open end of the tube. Drawing out a piece of "Jena Geräte Glas" tubing partly into a thin capillary, and inserting the sealed-off end of this tube into a rubber stopper, the length of the capillary was adjusted so that when the rubber stopper with the drawn-out capillary was inserted into the open end of the Pyrex tube, the end of the capillary was about 2 or 3 mm above the bottom of the Pyrex tube. Pieces of potassium were cut free from crusts and were quickly placed in the tube by taking out the rubber stopper with the capillary projecting into the tube, which was then immediately put back and the whole evacuated by attaching the side tube with the glass stopcock to a pump. After the tube and the capillary inside of it were well evacuated, the pieces of potassium, which were all placed along the side of the tube, were gently heated to cause the metal to melt and to flow to the bottom of the tube. The capillary was then dipping directly into the molten metal. The oxide, which could not be prevented from forming during the cutting of the pieces of potassium and their insertion into the tube, usually stuck to the walls of the tube or floated on the surface of the metal. By suddenly letting a sufficient amount of nitrogen into the tube through the glass stopcock connection, some of the potassium which was about 15 to 20° above its melting point was forced into the capillary and almost immediately solidified there. After allowing the tube to cool off, the stopcock was opened to relieve the vacuum, and the rubber stopper with the capillary was taken out. A suitable length of the capillary filled with potassium, which was approximately 0.5 mm in

diameter, was then sealed off at both ends. This was done by very quick heating and drawing out of the glass, and required for its successful accomplishment a little practice, as overheating caused the metal to react with the glass. This rather detailed description of the preparation of the samples is given on account of the disagreement of the present findings with the former investigations, and because it is thought that the reason for the different findings must lie in the preparation of the sample of potassium.

The samples prepared in this way, on exposure to X-rays by the powder method, were found to give diffraction spots, some only a few while others produced a considerable number of spots. It was quite obvious that this was due to the size and number of crystals present in the sample. To increase the number and reduce the size of the crystalline particles, heat treatment was resorted to. The samples were heated in water about 20° above the melting point of potassium and then quickly quenched by placing them in a salt solution at about -18° . A picture of a sample treated in this way showed a large increase in the number of diffraction spots. However, it seemed probable that the rate at which crystals of potassium grew would make it very difficult to obtain by quenching a sufficiently fine-grained preparation and no special attempt in this direction was therefore made. Instead, the well-known method of rotating the sample was used and heat-treated preparations were attached to a motor, which rotated them around their axis at the rate of a revolution per minute during the exposure to X-rays. In this way satisfactory diffraction pictures were obtained.

The diffraction data from potassium and its crystal structure. The diffraction apparatus used was one made by the General Electric Company¹ in which the $K\alpha$ radiation of molybdenum is used and in which the distance between sample and photographic film is eight inches. The time of exposure was normal, approximately 250 m.a.h. Sodium chloride was used as usual for the standardization of the spacings.

Spacing measurements of the diffraction lines recorded on a photographic film are given in the first column of Table I. The estimated relative intensities of these lines and the squares of the sines of their angles of reflection are given in columns two and three of the table. It is well known that the ratios of the $\sin^2 \theta$ should give for a cubic crystal values of whole numbers, which are usually small. As will be seen in column four this is the case within the limits of the experimental errors. These whole numbers represent the sum of $(h^2 + k^2 + l^2)$ and serve to assign the indices of the planes producing the diffraction lines (columns five and six). In the last column of Table I, the resulting value of the length of the edge of the unit cube is given for each observed diffraction line.

Photographs were obtained from several other preparations and all gave practically identical results. The average values of the length of the edge of the unit cube for each preparation are given in Table II.

Average value of a_0 from different samples.

Film number	a_0
135	5.335 Å
145	5.334
170	5.329
175	5.333

Average $a_0 = 5.333 \pm 0.005$ Å.

While not definitely established, it is probable that potassium crystallizes in the cubic system. A careful determination of the density of the alkali metals has been made by T. W. Richards and T. N. Brink¹, giving for potassium at 20° the value of 0.862. Introducing this value in the usual equation $a_0^3 = mM/\rho$, where a_0^3 is the volume of the cube, m the number of atoms of potassium within the unit, M the mass of the potassium atom and ρ the density of potassium, we find that $m = 2.02$. This is within experimental error a whole number, as it should be. Accepting, conversely, that two atoms are associated with the unit cell of potassium, the density of potassium calculated by the above formula assumes the value 0.851, which is in good agreement with the direct determination.

The only possible cubic arrangement for two like atoms in the unit cell is the body-centered one, with the coordinates: 000; $\frac{1}{2} \frac{1}{2} \frac{1}{2}$. The characteristic structure factor of the body-centered cubic lattice requires that the sum of the indices must be an even number for reflection. As may be seen from Table I this requirement is fulfilled and no other reflections occur.

We may further use the semi-empirical formula²

$$I \propto (A^2 + B^2) \times (d/n)^{2.35} \times j$$

¹ J. Am. Chem. Soc., 29, 117 (1907).

² Wyckoff: "The Structure of Crystals," 201 (1924).

to calculate for the different planes the intensity of reflection expected for the body-centered arrangement and compare these values, reduced to the same basis, with the estimates of the relative intensity made directly. The results in both cases are always only a rough approximation but a general agreement between the observed and calculated values will be readily seen from Table III, confirming further the correctness of the body-centered cubic structure.

TABLE III
Comparison between the observed and calculated intensities from the different reflecting planes of potassium.

123 (1)	2	4.1

Experiments with sodium and lithium. As mentioned above, a few samples of sodium and one of lithium were made and X-rayed in the same manner as were those of potassium. No difficulties were experienced in preparing samples of sodium, but lithium reacted very readily with the glass, probably owing primarily to its higher melting-point. After several attempts a sample of lithium was prepared, which, although it was not so good as those used with the other metals and although it produced considerable general blackening of the film, gave, however, four diffraction lines. In the former investigation of the structure of lithium by J. M. Bijvoet and A. Karssen¹ also only four diffraction lines were obtained and in view of the identical results it was not considered worth while to attempt preparing other samples. In complete agreement with earlier determinations, the length of the side of the unit cube for sodium was found to be 4.30 Å, and for lithium 3.51 Å.

Concerning general scattering from the alkali metals. Considerable stress has been laid on the general scattering obtained from the alkali metals, which was usually ascribed to the amorphous condition of the substance to a smaller or larger extent. The present experiments, while not carried far enough to find the direct cause of such scattering, strongly indicate that such an amorphous portion in all probability does not exist in the metal. Little if any general scattering was obtained from carefully prepared samples of potassium, and a comparison experiment showed that the amount was approximately the same as that produced by sodium chloride exposed in a similar glass capillary for the same length of time. The observations made seem to indicate that the general scattering is due rather to the formation of films produced by oxidation, moisture or the interaction of the alkali metals with the glass. Some samples of sodium which were probably overheated showed a slight

¹ Proc. Roy. Acad. Sci. Amsterdam, 23, 1365 (1921); Rec. Trav. chim., 42, 859 (1923).

discoloration and produced more of the general scattering than others, and the sample of lithium, which of course had to be heated considerably higher, produced accordingly a large amount of blackening on the film for approximately the same exposure.

McKeehan did not give any experimental data and it is therefore impossible to form a definite opinion in regard to the diffractions obtained by him from a sample of potassium kept at -150° during the exposure. However, the fact that nothing but general scattering was produced when the same sample was exposed at room temperature would, as a result of the present work, suggest that the weak diffraction obtained at -150° may possibly have resulted from the freezing out of some crystals of potassium hydroxide, which disappeared when the exposure was made at room temperature, owing to the melting of the crystals and formation of a liquid film.

Summary

Contrary to former statements, normal diffraction effects are obtained from potassium at room temperature by the powder method.

The reason for obtaining only a general scattering and no definite diffraction in former experiments is thought to be the formation of films on the sample of potassium by moisture, by oxidation, or by interaction of the potassium with the glass.

The method used for the preparation of samples of potassium is described.

The available data indicate that potassium crystallizes in the body-centered cubic lattice. The length of the edge of the unit cube containing two atoms of potassium is $5.333 \pm 0.005 \text{ \AA}$. The calculated density is 0.851 .

The lengths of the edges of the unit cubes of sodium and lithium were redetermined and, in agreement with earlier determinations, the value obtained for the former was 4.30 \AA and for the latter 3.51 \AA .

THE HEATS OF ADSORPTION OF CERTAIN ORGANIC VAPORS ON CHARCOAL AT 25°

BY J. N. PEARCE AND LLOYD MCKINLEY

While the adsorptive power of solid porous bodies for gases is a phenomenon that has challenged the attention of many investigators during the last century, the amount of quantitative data which has accumulated dealing with the heat effect accompanying adsorption is rather limited and is confined, for the most part, to the results of comparatively recent investigations. Although the thermal effect of adsorption had been observed by Mitscherlich¹ in 1843, Favre,² using a mercury calorimeter, was the first to make a quantitative measurement of the heats of adsorption of a number of gases on charcoal and of hydrogen on platinum. By the use of an ice-calorimeter Chappuis³ measured the heats of adsorption of sulphur dioxide, ammonia and carbon dioxide on charcoal, meerschaum, platinum black and asbestos. Dewar⁴, with the aid of a liquid-air calorimeter, measured the heats of adsorption of the permanent gases on charcoal at the temperature of liquid air. Homfray⁵ has shown that a certain thermodynamical formula is applicable for calculating the molecular heat of adsorption of carbon dioxide on charcoal. Using an ice-calorimeter, Titoff⁶ obtained consistent values for the thermal effect of adsorption of nitrogen, ammonia and carbon dioxide on charcoal. The heats of adsorption of sulphur dioxide and ammonia on silica gel have been measured by Patrick and Greider.⁷ Lamb and Coolidge⁸ have obtained values for the heats of adsorption of eleven organic vapors on charcoal. Whitehouse⁹ has measured the heat effect produced in the adsorption of carbon dioxide, methane and nitrogen on coals and charcoal. All of these investigators, with the exception of Favre, Homfray and Dewar, have made use of the ice-calorimeter. Beebe and Taylor,¹⁰ and Dew and Taylor,¹¹ have recently measured the heats of adsorption of hydrogen and ammonia, respectively, on copper and nickel by a rapid method in which the catalyst tube, itself, serves as the calorimeter. They do not, however, claim an accuracy better than 10 percent.

As can be noted from the above review of the literature, the majority of the measurements of the heats of adsorption, thus far, have been made at 0°.

Popular as the ice-calorimeter is, it does not permit an investigation at other temperatures. Except for the more difficultly liquefiable gases and vapors, most vapors condense to the liquid state at 0° . This, and the fact that in adsorption there may be a "forced" condensation, does not permit us to separate the thermal effects of the two kinds of condensation. Furthermore, until we are in possession of means of measuring the heat of adsorption at different temperatures, we shall not be able to determine experimentally the effect of temperature upon the heat of adsorption.

The purpose of this investigation was to devise and apply a calorimetric method for measuring the heats of adsorption at any desired temperature. By using higher temperatures we hope later to overcome certain difficulties which arise when working at the temperature of melting ice. Objectionable condensation effects will be avoided, and higher equilibrium pressures can be attained. Although we have not avoided condensation effects by working at 25° , we have, nevertheless, chosen it as our working temperature in this preliminary work. Measurements have been made purposely on some of the vapors studied by Lamb and Coolidge at 0° . In this way we hoped, by comparison, to show the accuracy attainable by the method.

Materials

The charcoal used in this investigation was taken from a large supply which has served as the basis of an extensive study of adsorption in this laboratory. It was prepared for us by the Carbide and Carbon Chemicals Corporation under the direction of Dr. N. K. Chaney. It is a coconut shell charcoal which has been activated by steam, treated with acid to remove mineral matter, and then washed until acid-free. The size of the granules used range from 12 to 20 mesh. Previous determinations showed the ash-content to be 0.28 percent by weight.

The loss in weight on outgassing and the density of the charcoal have been determined in an earlier work.¹² For the former, a weighed sample of the charcoal was evacuated under identical conditions employed in the regular adsorption experiments. When the pressure had remained constant at about 0.0001 mm. for several hours the tube was sealed off and weighed. The mean of three very concordant determinations showed a 2.50 percent loss in weight on outgassing; this correction was applied in calculating the actual weight of the adsorbent used. The density of the charcoal was determined by the method of Cude and Hulett,¹³ using water as the immersion liquid and disregarding the drift after the first few hours. The mean of four determinations, 1.800, was taken as the density and was used in correcting for the "dead space."

The liquids, whose vapors were studied, were purified carefully by accepted methods,¹⁴ and then fractionated. Only the middle portion of each fractionation was collected. These liquids were prepared immediately before using.

Apparatus

The apparatus is shown in Figs. 1 and 1a. It combines the advantages of recently improved adsorption apparatus with those of a calorimeter which may be used at any temperature. The net result is an apparatus more potential in possibilities than any, hitherto used in measuring the heats of adsorption.

FIG. 1

Adsorption Apparatus.—The adsorption apparatus consists of one continuous line of Pyrex tubing and flasks, with no stopcocks or rubber connections above the mercury levels; it is, essentially, in design and principle, the same as that used by Coolidge.¹⁵ For the sake of brevity, a detailed explanation

¹⁵ Coolidge: J. Am. Chem. Soc., 46, 596 (1924).

of the various parts is omitted. A detailed description of the apparatus and its operation is given in the original paper.

Calorimeter.—The calorimeter, R, is a wide-mouth Dewar flask, fitted with a cork stopper with openings for the charcoal bulb, G, the spiral rotary stirrer, P, one arm of the thermocouple, Q, and a special low lag heating coil, N.

FIG. 1a

The charcoal bulb of "702 P" Pyrex glass, Fig. 1a, G, contains a spiral and a straight piece of tungsten wire, both sealed into the bottom of the bulb so that about 2 cms. protrude. The wires within the bulb are so arranged that the distance between the adjacent wires does not exceed 3 mm. In this way the heat liberated in the adsorption process is quickly conducted from the charcoal surface to the calorimeter liquid.

Constant Temperature Bath.—The complete apparatus with the exception of the bulb, A, is inclosed in a double-walled, electrically heated and electrically controlled air-bath mounted on a heavy table. Efficient stirring is obtained by a system of high-speed fans which maintain a continuous and rapid circulation of air through the bath, over the cooling coils at the top, then down between the walls at the sides, and finally past the low lag heating coils into the bottom of the bath. This efficient circulation of the air, together with a 5-foot upright multiple-tube mercury regulator in series with a Bunnell relay, enabled us to control the temperature of the bath to within $\pm 0.05^\circ$. At the front and back are large double doors which provide, not only a non-conducting air space, but also a ready means of accessibility to the apparatus when in need of alteration or repairs. The glass doors at the front permitted readings of the bath temperature and of the vapor pressures by means of a cathetometer placed outside. Ideal working conditions were realized by means of a special precision system of mercury controlling devices operated from a panel of convenient switches on the front of the table.

The volume of the reservoir, B, together with the connecting tube to the mark between valves 4 and 5, and thence to the mark on C, was determined from its water capacity before the apparatus was assembled. The volume of the charcoal bulb, G, plus the capillary tube to the mark on E, was likewise calibrated with mercury before assembling.

Thermo-element.—The 25-junction copper-constantan thermo-element was made in strict accord with the specifications given by White.¹⁶ The element was accurately standardized against a certified thermo-element at three points, namely, the transition points of $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ and $\text{MnCl}_2 \cdot 2\text{H}_2\text{O}$, and liquid air. The salts were carefully purified according to the methods of Richards and Wrede,¹⁷ and of Richards and Wells,¹⁸ respectively. The reference ice bath consisted of a large Dewar flask containing pure ice moistened with conductivity water. Since the thermal measurements made in this work were at 25° , we have calculated the potentials corresponding to 25° and 26° . They were found to be $22856\mu\text{v}$ and $23802\mu\text{v}$, respectively; the difference corresponds to 0.0010559° per $1\mu\text{v}$.

Thermal Capacity of the Calorimeter.—The calibration of the calorimeter system with water as the calorimeter liquid was made electrically by passing an accurately known quantity of electricity through a heating coil of known resistance. This coil consisted of about 100 cms. of No. 36 constantan wire wound around a thin mica strip. It was insulated by two similar strips of mica and inclosed in a close fitting copper case. Two heavy insulated copper leads pass from the case, proper, through a short metal tube that is cemented to a glass tube, which serves as a handle and as a heat insulator. The metallic parts of the receptacle, which is made air tight by soldering, is heavily plated with silver and polished. The resistance is 52 ohms, and in operation delivers about 3 watts.

¹⁶ White, J. Am. Chem. Soc., **36**, 2292 (1914).

¹⁷ Richards and Wrede, Z. physik. Chem., **61**, 313 (1907).

¹⁸ Richards and Wells, Z. physik. Chem., **43**, 465 (1903).

Method of Calibration.—The heating coil was connected in series with a standard 1-ohm resistance, a laboratory slide rheostat and a very sensitive Bradleystat. A battery of seven large storage cells supplied the current. Across the standard ohm and the heating element were connected a Leeds and Northrup, "Type K," potentiometer and a volt-box, respectively. With this arrangement, the potentiometer reads directly in amperes, whereas the volt-box in conjunction with a student potentiometer permits the reading of the volts. With the potentiometer set to read the amount of current chosen to flow through the system, the rheostat was adjusted so that a slight manipulation of the Bradleystat enables the operator to maintain a current whose variations at any instant never exceed 1 part in 1000. A sensitive galvanometer indicated the deviations which can be instantly corrected. The voltage drop across the heating coil was read at intervals of one minute, and was found to be practically constant. When the voltage did actually vary, the average value during the interval was calculated and used. The time of passage of the current was measured by means of a stop watch, reading to 0.2 sec.

The increase in temperature during a calibration, although small, corresponded to an increment of approximately 2000 μ v. Since the galvanometer was responsive to deviations of 1 μ v., the possible error in this measurement was not greater than 0.1 percent. Radiation, though perceptible, was measurable. The magnitude of the radiation was greatly reduced by starting the calibration at a calorimeter temperature that was as far below, as the final temperature was above, that of the constant temperature bath.

The results of two determinations of the thermal capacity of the calorimeter and its fixtures were 51.26 cal. and 51.42 cal., with a deviation from the mean, 51.34 cal., of less than 0.2 percent. The value of 51.34 cal. was accordingly accepted as the thermal capacity of the calorimeter and was used in all subsequent calculations.

Specific Heat of "Finol."—Following the same procedure as outlined for water, we obtained the thermal capacity of the calorimeter system and liquid when charged with an accurately known weight of a light oil, which is sold under the trade name of "Finol." With 300 cc. of this oil in the calorimeter, the total heat capacity is only about 165 cal., an amount which is less than one-half that with an equal volume of water as the liquid. Three different determinations of the specific heat of the oil, in calories, over the range from 25° to 28°, gave the values 0.4500, 0.4492 and 0.4512, respectively, or a mean specific heat of 0.4501 cal.

Sensitivity of Calorimeter

The thermal capacity of the calorimeter and liquid is equal to the thermal capacity of the calorimeter, (51.34), plus the product of the weight of the oil times its specific heat, 0.4501 cal. For the average weight of oil used, this amounts to 165 cal. Since the thermo-couple used was sensitive to 0.001°, the calorimeter system responds to a heat transfer of 0.17 cal. In using the ice calorimeter for their measurements, Lamb and Coolidge state that on their

scale a millimeter movement of the mercury thread, during the change of state from ice to water, corresponds to 0.589 cal. Hence the resulting sensitivity of the ice calorimeter is three times that of our calorimeter, if the displacement of the mercury thread can be read to 0.1 mm. The results of our work show, however, that this difference in sensitivity is not appreciable.

Experimental Method

The charcoal bulb, first weighed empty and then full of charcoal, is sealed into position, inclosed in an electric furnace at 550°, and evacuated until the McLeod gage, (not shown in Fig.), indicates a pressure of 0.0001 mm., or less. All of the mercury levels are lowered so that the whole system is evacuated at the same time. Mercury well, L, is now raised, closing valve 1, the pumping is discontinued and the furnace is allowed to cool. The procedure involved in charging A with liquid and B with vapor, as well as that involved in transferring the vapor to the charcoal, if not evident to the reader, can be found in the paper by Coolidge,¹⁵ who worked with a similar apparatus. An additional feature is a reservoir used when the transfer of large volumes of vapor is required to produce high equilibrium pressures. This consists of a mercury well and bulb (not shown), but attached to the capillary, H.

The calorimeter is charged with a weighed amount of oil, initially at or very near the temperature of the bath, and is allowed to stand with intermittent stirring until a constant reading of the thermo-element is obtained. When thermal equilibrium is attained and the cathetometer pressure readings become constant, a sample of the vapor is transferred to the charcoal by means of the pump, D. After the admission of the vapor to the charcoal, the liquid is stirred intermittently for periods of one to three minutes. During this time the thermo-element potentials are read at one minute intervals until the potential attains a constant value, or until a constant rate of radiation is indicated. Pressure readings are then taken of the vapor remaining in the reservoir, and of the vapor in equilibrium with the charcoal. Once the equilibrium is established and the data recorded, a new sample of vapor is admitted. With each admission of vapor, there are recorded the potential increments in microvolts, the corresponding drop in the presence of the vapor in B, and the successively increasing equilibrium pressures over the charcoal. When the equilibrium pressure has attained a value just short of that at saturation a series of adsorption experiments, or "run," is assumed to be completed.

Calculation of Results

The results are expressed in small calories and cc. of gas (N.T.P.) per gram of gas-free charcoal. The vapor pressures were corrected for altitude and temperature, and the gas laws were applied in calculating the volume of the vapor. The complete calculations of an experiment are given below.

Weight of charcoal and glass bulb.....	28.6705 g.
Weight of bulb.....	25.5844 g.
Weight of charcoal.....	3.0861 g.

Corrected weight of charcoal ¹³	3.0089 g.
Volume of total reservoir system (N.T.P.).....	2203.6 cc.
Pressure in B before adsorption.....	9.775 cm.
Pressure in B after adsorption.....	8.755 cm.
Drop in pressure.....	1.020 cm.
Correction for temperature and altitude.....	0.005 cm.
Corrected pressure drop in B.....	1.015 cm.
Gas removed (per g. of char.) for 1 cm. drop in pressure:....	

$$\frac{2203.6 \times 273}{76 \times 298 \times 3.0089} = 8.828 \text{ cc.}$$

For 1.015 cm. drop the cc./g. removed is.....	8.96 cc.
Pressure in charcoal bulb at equilibrium.....	0.00 cm.
Volume of bulb and tubing to calibration marks.....	14.900 cc.
Volume of charcoal: 3.0089 + 1.800.....	1.671 cc.
Volume of "dead space".....	12.229 cc.

$$\frac{13.229 \times 273}{76 \times 298 \times 3.0089} = 0.053 \text{ cc./g.}$$

(Gas removed but not adsorbed.....)	0.00 cc./g.
(Gas adsorbed "x".....)	8.96 cc./g.
Initial reading of thermocouple at 7.46 P.M.....	22874 μ v.
Time required to introduce vapor: 7.46 to 7.52.....	6 min.
Stirrer started at 7.52 (60 R.P.M.)	

Time	Thermocouple reading
7.54	22941 μ v.
7.55	22958 μ v.
7.56	22965 μ v.
Rate of stirring decreased (30 R.P.M.)	
7.57	22970 μ v.
7.58	22975 μ v.
Stirrer stopped.	
8.00	22979 μ v.
(At this time pressure readings were taken)	
8.13	22996 μ v.
Stirrer operated 1 min.	
8.15	22990 μ v.
8.16	22990 μ v.
8.19	22990 μ v.
Final reading of the thermocouple.....	22990 μ v.
Increase in microvolts.....	116 μ v.
Weight of oil in calorimeter.....	252.66 g.
Cal./g. evolved corresponding to increase of 1 μ v:	

$$\frac{(252.66 \times 0.4501) - 51.34}{947 \times 3.0089} = 0.057927 \text{ cal./g./} \mu\text{v.}$$

Total heat evolved per gram of charcoal, "h": $116 \times 0.057927 = 6.72 \text{ cal./g.}$

The results of each experiment, namely, the drop in pressure and the heat evolved are added to those of the preceding experiments of the same run, thus giving the total heat evolved, h , and the total drop in pressure in B, during the adsorption of the vapor. This change in pressure enables us to calculate the total gas volume, x , adsorbed by the charcoal.

Results

The results of the study of the heats of adsorption of nine vapors on charcoal are recorded in the following Tables. The first column in each gives the equilibrium pressure observed at the time when the final calorimeter reading

was made. The second column gives the volume of gas in cc. (N.T.P.) adsorbed by 1 g. of gas-free charcoal. In the third are placed the increase in the thermocouple reading, in μv , accompanying the transfer of the vapor. These readings, converted to calories, Δh , are listed in the fourth column. The fifth contains the summation, Σh , of the heat effects of the previous additions of the same series. In the sixth are placed the values of Σh calculated by means of the exponential formula, placed at the bottom of the table. The previous history of the sample is also given below the results for each liquid.

Used in expts. VI, VII and VIII. $h = 0.9441 \times 10^{9915}$.

If the observed values of X and h are plotted, we obtain curves which are slightly concave toward the X -axis. Fig. 2 shows the curves for all of the vapors drawn from a common origin. In order to prevent overlapping, a plot is made in which the origin is displaced one square with respect to the

FIG. 3

next one to it, giving the system of curves in Fig. 3. The data obtained by Lamb and Coolidge at 0° are also indicated by the points, x . When the values of $\log n$ are plotted against the corresponding values of $\log x$, we get the curves in Fig. 4, from which the experimental values show slight, if any, deviations. From the position and slopes of these lines, (Fig. 5), we obtain the constants of the equation:

$$\log h = \log m - n \log X, \text{ or } h = m X^n.$$

The constants obtained in this way have been used to calculate the values of h which are given in the sixth column of each Table. In the seventh col-

umn are placed the differences, Δ , between the observed and calculated values. In case that more than one series of experiments was made with the same vapor, the same sample of charcoal was used. The fact that all of the points fall almost exactly upon the curve shows that the vapor is without influence upon the adsorption power of the charcoal.

FIG. 4

Reproducibility and Reliability of Results

The results presented in Tables I to IX, and in Figs. 2 to 5, have been obtained with various weights of charcoal, some fresh, others previously used, and with variations in time and quantity of vapor admitted to the charcoal. The agreement between data on a fresh sample and on one which has been used is excellent. The agreement between duplicate runs for a given liquid is as good as that between the individual experiments. This is shown by Figs. 3 to 6. At most, the deviations are very slight. In general, the data of Lamb and Coolidge, indicated by points, x , are seen to be in close agreement.

These observations indicate that the total quantity of heat evolved during adsorption by gas-free charcoal is definite and reproducible. It is not affected by the manner in which the vapor is added, whether it is added slowly or rapidly, all at once, or in small portions. It is independent of the previous

history of the charcoal, provided the charcoal is previously evacuated at 550° . The calorimeter reading usually indicated adsorption equilibrium within eight to twenty minutes, and no appreciable "creeping" was ever observed. Vapors, such as carbon tetrachloride and chloroform, which are known to

FIG. 5

poison charcoal, do not appear to reduce appreciably the quantity of heat evolved when a given volume of vapor is adsorbed in a subsequent run on the same sample. This is contrary to the observation of Lamb and Coolidge, who report that vapors studied with poisoned samples of charcoal give values for the heat evolved which are about 10 percent lower than with fresh samples.

Discussion of Results

In attempting to calculate the molecular heat of adsorption, h_m , from the data, we might simply solve for h in the equations,

$$h = mX^n,$$

after substituting for X , the volume of a gram molecule of the vapor, 22.410 cc., and making use of the characteristic constants, m and n , obtained from the logarithmic plot. The resulting value for h , which would be the molecular heat of adsorption per one gram of charcoal, is impossible from a practical standpoint. In arriving at their values for h_m , Lamb and Coolidge chose to express it as the heat evolved when one mol of vapor is adsorbed by 500 g. of charcoal. This choice follows directly and conveniently from the fact that 1/500 mol of vapor is equivalent, in cc., to the average mid-point of the range of volume of vapor adsorbed by one gram of their charcoal. This mid-point they designate as 44.6 cc. In order the better to compare the results obtained by the two methods, we have made our calculations on the same basis as that used by Lamb and Coolidge. The results obtained by both methods are given in Table X. In making this comparison we must bear in mind that we have no knowledge of the mineral content of the charcoal which they have used.

*Estimated.

Since the ground covered in this work is practically the same as that covered by Lamb and Coolidge, we can, in the discussion of these results, as well as of those that follow, do little more than make a comparison of the results obtained at the two temperatures by two entirely different methods. Perhaps the most striking relation to be observed in Table X is that for the calculated values of the molecular heats of adsorption, h_m . Except for ethyl chloride, methyl alcohol and benzene, the values are almost, if not identical. The molecular volume of ethyl chloride at 25° had to be estimated, and, hence, calculations depending upon it should have little weight. Omitting ethyl

chloride and carbon bisulphide, the values of h_m calculated for 25° do increase with increase in the molecular volume of the liquid. It will be observed also that the value of n is always less than unity. Even including the value of n for benzene, the maximum deviation from the mean value, 0.918, is only 5.6 percent. The values of m vary much more widely than do those of n , and, furthermore, there is a decided tendency for m to be small when n is large. Except for chloroform, the values of these constants seem to be dependent upon the temperature. In general, as the value of m increases with the temperature that of n decreases. The reverse relation is equally true. Lamb and Coolidge⁸ have shown by a graph that there is a decided relation between the values of $1-n$ and the boiling points of the liquids. They state that this parallelism indicates that the higher the boiling point of the liquid, the less marked is the "fatigue." No parallelism between n or m and any physical property of the liquids is directly apparent from our data.

No final conclusion as to the effect of temperature upon the molecular heat of adsorption can be drawn from the comparison of the data obtained at 0° and 25°. It suffices to say that the effect of temperature, in general, is not marked.

From a theoretical standpoint, the views regarding the effect of temperature upon the heat of adsorption are conflicting. In the first place, according to Lorentz and Lande,¹⁹ but in opposition to the views of Eucken,²⁰ the adsorption potential, which is really the heat of adsorption, should, in general, vary with the temperature. Secondly, it can be shown that the isosteres, obtained by plotting the values of the $\log p$ against the reciprocal of the absolute temperature, are in general for any one vapor linear and parallel, and, therefore, are of the same slope. If the value of $Rd \ln p/d(1/T)$ does not vary with the temperature, we should expect the heat of adsorption to be independent of the temperature and concentration. One objection to the use of the isosteres as a means of calculating the heat of adsorption is the fact that the values thus calculated are often too low and they do not include that appreciable part of the range of adsorption where p is too small to be measured accurately.

Lamb and Coolidge⁸ maintain that the process of adsorption may be considered as taking place in two steps: first, a compression of the vapor to such a point that liquefaction ensues, and second, a further compression of this liquid by the attractive forces of the adsorbent. The observed heat of adsorption will then be made up of two quantities, the heat of vaporization of the liquid, and that which may be designated as the *net* heat of adsorption. The latter quantity they showed to be proportional to the heat of compression of the liquid under high pressure. In accordance with this theory, the effect of temperature upon the heat of adsorption will be the result of two effects: one upon the heat of vaporization, and the other upon the heat of compression.

The molecular heats of adsorption of each of the nine vapors have been calculated for 25°. They are included with related data in Table XI. The

Mean deviation				+7.4%		±10%		±4%

In general, the net heats of adsorption are, for the most part, of the same magnitude as the heats of vaporization. They vary from half as much for methyl alcohol to a half more for ether and propyl chloride. While the heats of vaporization of all liquids are less at 0° than at 25° , the net heats of adsorption are greater at 25° than at 0° . The one exception to this rule is ethyl chloride. This exception may be apparent, rather than real, since the calculation of h involved the calculation of the molecular volume of ethyl chloride as a liquid at 25° . The value of Q , the heat of vaporization, of ethyl chloride, may also be in error, since its value was obtained from existing vapor pressure data. Lamb and Coolidge report the heat of vaporization of benzene at 0° to be 7.81 K. cal. This value is much smaller than the values²¹, 8.28 and 8.51, as given by Regnault and Young, respectively. The data obtained by these two investigators is given in Table XII for comparison.

The net heats of adsorption per 1 cc. of liquid on 10 g. of charcoal at 25° , (Col. 5), were obtained by dividing the net molecular heat of adsorption by the molecular volume of the liquid at 25° . It is evident that these net heats of adsorption per 1 cc. of liquid are all very nearly the same, the average deviation from the mean, 0.0969 K. cal., being only 7.1 percent. Except for ethyl chloride, these net heats per cc. are all higher than the corresponding values at 0° by about 10 percent. The mean deviation is practically the same at both temperatures. Such a small deviation led Lamb and Coolidge to believe that the net heats of adsorption must be due to the attractive forces of the charcoal, and that for a given amount of capillary space the heat liberated is identical, or nearly so, for all liquids.

Following the methods of our predecessors, we have calculated the heat of compression, in small calories, per atmosphere per cc. of liquid at atmospheric pressure. This calculation was made by the use of the relation:

$$\frac{dQ}{dT} = \left(\frac{dv}{dP} \right) : \frac{T}{42.7}$$

The values of $\frac{dv}{dT}$ were obtained by substituting the values of the temperature and the constants in the expression obtained by differentiating series formulae of the type: $v_t = v_0(1 + \alpha t + \beta t^2 + \gamma t^3)$, as given in the Landolt-Börnstein Tables. In every case the values are somewhat higher than the corresponding values at 0° . This seems highly significant, since it may afford an explanation why the heat of adsorption might not change with temperature. That is, the change in the heat of vaporization may be compensated by a corresponding change of opposite sign in the heat of compression.

The quotients of the net heats of adsorption divided by the heats of compression give us the attractive forces of the charcoal acting on the various liquids. These quotients are given in column 7 of Table XI. The average value of the attractive forces is about 10000 atmospheres. The comparison of these values with those obtained for 0° show clearly that these forces are diminished with rise in temperature, and in some cases markedly so. Because

²¹ Landolt and Börnstein: "Tabellen."

of this high pressure, Lamb and Coolidge state that we are not justified in using heats of compression at 1 atmosphere in making these computations; that instead we should use the mean heats of compression obtained by integration over the whole pressure range covered. They have calculated the attractive forces of some of their vapors at 0° from the heats of compression computed by Bridgman²² at pressures up to 12000 atmospheres. Five of our vapors were studied by Bridgman at 20° , 40° , 60° and 80° . The values of the heats of compression at 25° have been interpolated and are given in column 8. The average value is about 12 percent higher than at 0° ; the individual values show an even greater constancy.

If we now divide the net heats of adsorption by these better values of the heats of compression, we obtain the attractive forces given in column 9. The average value of the attractive force of carbon for these five vapors is 29000 atmospheres, or about 3.1 percent higher than for the average of the seven studied at 0° . The rather considerable increase in the attractive force of carbon for methyl alcohol and ether is significant.

Whether or not the attractive force exerted by charcoal on all liquids is the same and independent of the temperature is still a question. We know relatively little regarding the conditions prevailing in liquids under high pressures. Furthermore, we know still less of the conditions existing when these liquids are under high pressures and at the same time in contact with the attractive forces of a powerful adsorbent. For example, Bridgman states that pure acetone solidifies at 20° when under a pressure of 8000 atmospheres. At what temperature would it solidify under this same pressure when in contact with porous charcoal? This we cannot answer.

Summary

1. A new calorimetric method has been devised by which it is possible to measure heats of adsorption at any temperature. It permits the use of temperatures at which the liquid phase is absent, and thus prevents the introduction of the thermal effect due to ordinary condensation.

2. The method possesses three important features. (a) Objectionable condensation effects are eliminated by having the calorimeter at the same temperature as that of the vapor to be adsorbed. (b) The charcoal bulb is of such a design that the heat evolved is quickly conducted outward to the calorimeter liquid. (c) The rise in temperature of a known weight of oil is read by a sensitive thermoelement.

3. The heats of adsorption of nine vapors on charcoal have been measured at 25° . The heat effects were found to be easily reproducible, and they are independent of the rate of adsorption of the vapor and of the previous history of the charcoal.

4. The heats of adsorption of these vapors are in close agreement with those obtained by Lamb and Coolidge for the same vapors at 0° .

THE ROLE OF PHOSPHATES ON THE TAKING UP OF DYES BY MORDANTS

BY CHARLES E. WHITE AND NEIL E. GORDON

Many attempts have been made to advance a satisfactory theory to explain the effect of salts upon the dyeing process, but none of these have proved entirely satisfactory. One reason for this seems to be the lack of quantitative data based on investigations in which sufficient attention has been given to a control of the variables. The object of this investigation was to obtain quantitative data under such carefully controlled conditions that it might be possible to determine definitely the effect of phosphates on the taking up of dyes by mordants.

Materials used

The hydrous oxide gels of iron, aluminum and chromium were used throughout the experiment. These were prepared by dissolving seventy-five grams of the respective chlorides in five liters of water at a temperature of fifty degrees centigrade and then very dilute ammonium hydroxide was added until all of the metal had precipitated. The gel was washed free from chlorides by decantation. This usually required six or seven days. In most of the experiments the gel was used mixed with such a quantity of water that it could be readily drained free from a fifty cubic centimeter pipette from which the tip had been cut off in order to allow passage of the large particles of gelatinous material. Where it was objectionable to have such a large quantity of water present the gel was filtered by suction until all the water possible had been removed. The gel in the resulting condition was weighed up on the balance in a stoppered weighing bottle. The silica gel was furnished by the Davison Chemical Company. Before using, it was ground small enough to pass a one hundred mesh sieve, washed by decantation and allowed to dry at room temperature.

The water content of the gel was determined by heating a sample for twenty-four hours at 105° C. The iron, aluminum and chromium gels that were in a condition to be measured in a pipette contained about 98 per cent water.

The dyes were donated by E. I. du Pont de Nemours and Company. The acid dye, Orange II, is a sodium salt and the basic dye Crystal Violet is a chloride, potassium di-hydrogen phosphate, the salt, was J. T. Baker's C. P. material.

Experimental Procedure

In the adsorption of dyes by gels Gordon and Marker¹ have shown that equilibrium is reached if the dye and the gel are heated to 100° C for two hours with frequent shaking. Gordon and Starkey² have shown that in order to

¹ Ind. Eng. Chem., 16, 1186 (1925).

² Soil Science, 14, p. 449 (1922).

obtain maximum adsorption of potassium di-hydrogen phosphate by inorganic gels the mixture must be shaken almost continuously for seventy-two hours. Thus when it was desired to have comparable results with both the dye and phosphate, the solutions were put into 250 cc. ground-glass stoppered bottles, heated at 100° for two hours, then shaken continuously for three days in a mechanical shaker.

After this the solution was analyzed for materials unadsorbed. The solution was separated from the gel by an ultra filter. This was made by pouring the mixture of gel and solution over a filter paper until the paper had become thickly coated with gel. The whole solution was then filtered through this.

Determination of Adsorbed Materials

The adsorption was determined by analyzing the solution before mixing with the gel and then again after adsorption had taken place. The difference between these determinations was called the amount of material absorbed. The dye was determined by titration with titanium tri-chloride according to the general directions in Knecht and Hibbert's "Manual of Volumetric Dye Analysis." Specific directions were furnished by E. I. du Pont de Nemours and Company. Their directions are as follows:

"DuPont Orange II: Dissolve .2 gms. dye in 100 c.c. water and 35 c.c. of sodium tartrate (25%). Boil gently three minutes and titrate hot under CO₂ with .05N TiCl₃ solution. The final color change is from red to gray or brown and is sharp. The titration should be carried out slowly as the end point is approached."

In determining potassium, and the phosphate radical in Orange II solutions, it was necessary first to remove the dye by precipitation with HCl or to decompose it by boiling with aqua-regia. Both methods were used and the latter found to be the most satisfactory. The potassium was determined by precipitation with platinic chloride according to the Lindo-Gladden method. The phosphate was determined by the ammonium molybdate method. In the case of Crystal Violet the dye was removed by precipitation with sodium hydroxide.

The hydrogen ion concentration of all clear solutions was determined by means of the Bailey Electrode. A normal calomel electrode was used with this and the readings taken on a Leeds and Northrup "Student Type" potentiometer.

In order to obtain the pH of the dye solutions and of solutions containing any colloidal material a modified form of the Hildebrand type electrode was used. The electrode was a single platinum wire coated with platinum black. Before using this it was saturated with hydrogen by electrolysis in a sodium hydroxide solution. It was found that this treatment insured much steadier readings in dye solutions. In making a determination the solution was saturated with hydrogen before the electrode was immersed in it. For Crystal Violet solutions and clear solutions the readings of this electrode could be checked with those of the Bailey electrode. But with Orange II solutions this is not true. With Orange II all readings were determined in duplicate on the

electrode described above as soon as a steady reading could be obtained after the electrode was immersed in the solution. While it is not claimed that these values are absolute, they are the best it is possible to obtain under these conditions and they allow excellent comparison for this work.

The Adsorption of Crystal Violet by Silica, Iron and Aluminum Gels in the Presence of Phosphates

Tables I-VI show a comparison of the Crystal Violet dye adsorbed with KH_2PO_4 present and when no salt was used. In these experiments the pH was varied by using sulphuric acid and sodium hydroxide. The solutions used were .05 per cent dye and 0.5 N KH_2PO_4 .

6.85	6.54	449.1	18.0

TABLE III

The Effect of Phosphates on the Adsorption of Crystal Violet (a basic dye) by Iron Gel

pH of salt solution	pH of bath after ads.	Mgm. dye ads. per gm. dry gel	
		KH_2PO_4 present	without salt
2.59	5.27	378	28.0
4.45	6.04	460.9	40.0
6.12	6.14	886.8	46.2
6.49	6.42	1041.4	47.5
6.85	6.81	1118.3	48.0

It is seen from the above data that the effect of the phosphate salt added is to increase the adsorption of the basic dye. The pH could not be carried any higher due to the dye precipitating out of solution. Iron gel seems to be the best adsorbent for the basic dye and as will be noted in the following tables it is also the best adsorbent for phosphates. Both the potassium and the phosphate adsorbed in the above experiment were determined. The data are for all three gels.

TABLE IV

The Effect of Crystal Violet Dye on the Adsorption of Potassium Acid Phosphate by Silica Gel

2.75	—0.5	—0.3	—0.16	—1.6
3.14	—0.1	—0.1	—0.13	—1.4
3.16	0.1	—2.0	0.01	—1.5
4.43	0.2	—2.3	0.5	—0.2

TABLE V

The Effect of Crystal Violet Dye on the Adsorption of Potassium Acid Phosphate by Aluminum Gel

pH of bath after ads.	Mgm. adsorbed per gram of dry gel.			
	PO ₄ ads. dye present	PO ₄ ads. no dye	K ads. dye present	K ads. no dye
2.91	127.8	318.5	4.4	4.7
5.36	124.9	249.0	7.1	9.4
5.98	110.9	233.0	11.4	10.6
6.12	101.2	227.5	9.4	10.8
6.30	104.3	223.3	9.5	11.1
6.54	98.8	218.0	9.9	11.5

TABLE VI

The Effect of Crystal Violet Dye on the Adsorption of Potassium Acid Phosphate by Iron Gel

pH of bath after ads.	Mgm. adsorbed per gram of dry gel			
	PO ₄ ads. dye present	PO ₄ ads. no dye	K ads. dye present	K ads. no dye
5.27	272.5	—	17.9	—
6.04	254.2	—	26.1	91.0
6.14	258.6	—	28.7	90.0
6.42	247.3	339.0	30.2	82.0
6.81	255.6	276.0	28.1	76.0

In every case it is shown that even though the dye is very much more highly adsorbed with the phosphate present, the PO_4 adsorption is not great enough to account for the high adsorption of the dye. It is believed that the salt increases the size of the dye particle to colloidal dimensions and then it is merely filtered out of solution by the gelatinous particles of metallic oxides.

It will be noted in subsequent data that the action of phosphates with acid dyes is directly opposite to that with basic dyes.

Adsorption of Orange II (an acid dye) by Silica, Iron, Aluminum and Chromium Gels

With silica gel there was no adsorption of the acid dye Orange II either with or without a salt present.

Table VII shows that with aluminum gel the adsorption of Orange II was greatly decreased by the presence of the phosphate. In this experiment the pH was varied with sulphuric acid and sodium hydroxide. The solution used was 0.5 per cent dye and 0.05 N KH_2PO_4 .

TABLE VII

The Effect of Potassium Acid Phosphate on the Adsorption of Orange II by Aluminum Gel

pH of original salt solution	Final pH of bath	Mgm. dye ads. per gm. dry gel.	
		Phosphate present	no salt present
2.68	5.05	38	279
3.18	5.51	26	186
3.38	5.43	27	185
4.48	5.73	15	177
6.49	6.02	14	170
7.02	6.56	1	166

This data are illustrated more vividly in Fig. 1.

It is remarkable that the small amount of salt added to the dye bath should make such a marked decrease in the adsorptive power of the gel. It might be expected that the gel has preferentially adsorbed the phosphate, but the following data show that there is also a great decrease in the phosphate adsorption.

TABLE VIII

The Adsorption of Potassium Acid Phosphate by Aluminum Gel in the Presence of Orange II Dye

pH of bath after ads.	Mgm. adsorbed per gm. of dry gel			
	PO_4 ads. dye present	PO_4 ads. no dye	K ads. dye present	K ads. no dye
5.05	143.0	258.5	00	9.0
5.51	117.6	244.0	00	9.8
5.43	105.8	247.5	00	9.7
5.73	96.7	238.0	4.67	10.2
6.02	75.7	231.5	6.12	10.6
6.56	46.3	217.5	—	—

A comparison of the phosphate adsorptions is given in Fig. 2.

The great decrease in the adsorption of the phosphate cannot be balanced by the very slight adsorption of the dye. The same phenomenal decrease in adsorption is noted in the following data on iron gel.

FIG. 1
Adsorption of Orange II by Aluminum Gel

TABLE IX

The Effect of Potassium Acid Phosphate on the Adsorption of Orange II by Iron Gel

pH of original salt solution	pH of bath after ads.	Mgm. dye ads. per gm. dry gel	
		phosphate present	No salt present
2.75	6.09	00	225
3.16	6.25	00	80
4.66	6.42	00	70
6.54	6.60	00	63
7.05	6.79	00	62

The phosphate and potassium adsorption was also decreased below normal even though no dye was adsorbed.

TABLE X

The Adsorption of Potassium Acid Phosphate by Iron Gel in the Presence of Orange II Dye

pH of bath after ads.	Mgm. ads. per gram of dry gel.			
	PO_4 ads. dye present	PO_4 ads. no dye	K ads. dye present	K ads. no dye
6.09	211.1	—	21.4	91.0
6.25	200.5	—	24.3	88.0
6.42	188.6	340	25.1	83.0
6.60	160.3	330	23.6	80.0
6.79	130.6	319	19.1	74.0

In order to determine whether this decrease in adsorption was due to the PO_4 ion alone or to other ions present, an experiment was run where phosphoric acid was added to the dye solution. Varying amounts of the acid were used in order to vary the pH. Of course there might be expected a change in adsorption due to the varying concentration of the negative radical. In the following experiment one gram of Orange II dye was dissolved in 200 cc. of phosphoric acid solutions and added to 1.02 grams of gel.

FIG. 2
Adsorption of Phosphate by Aluminum Gel

TABLE XI

The Effect of Phosphoric Acid on the Adsorption of Orange II by Iron Gel

Final pH of bath	Mgm. per gram of dry gel.		
	PO_4 originally present	PO_4 ads.	Dye ads.
4.30	263.5	233.5	00
4.85	217.8	202.9	00
5.16	164.0	153.9	00
5.29	102.9	97.9	00
5.36	92.3	86.6	00
5.44	61.9	58.7	00

Table XI shows conclusively that the elimination of the adsorption of the dye is due to the phosphate and not to the presence of other ions.

Having established the fact that the phosphate was the effective agent in decreasing the adsorption of the dye it became our problem to determine if possible just why the phosphate should do this.

Gordon and Marker¹ have shown that the taking up of Orange II by aluminum and iron gels is a chemical reaction and not merely a case of surface adsorption. According to this then the observed facts should offer explanation either on the basis that the phosphate is acting on the gel and preventing its reaction with the dye, or it is acting upon the dye in solution in such a manner that it prevents the reaction taking place.

¹ Ind. Eng. Chem., 16, 1186 (1925).

Taking the latter idea first, it was thought possible that the phosphate might have an effect of increasing the solubility of the dye in solution and thus making its taking up by the gel more difficult. So an experiment was run to determine this. It was found that at the concentrations of phosphates used in the experiment there was no detectable influence upon the solubility. But if a large quantity of phosphate is added, the solubility of the dye decreases and the dye may be precipitated out of solution. This would have the effect of increasing the adsorption by gels rather than decreasing it. Another thought was, that owing to a change in the thermodynamic environment of the solution on the addition of phosphate, it might take a longer time for the dye and gel to reach equilibrium. So an experiment was run in which the dye was allowed to remain in contact with the gel for a period of six months. Samples were removed at intervals for analysis.

Solutions of 0.5 per cent Orange II dye and .05 normal potassium dihydrogen phosphate were mixed with 1.08 grams of gel. This mixture was heated to boiling for four hours and placed in a mechanical shaker and agitated. This treatment was repeated at frequent intervals over a period of six months. The pH was varied with phosphoric acid and potassium hydroxide.

TABLE XII

The Result of allowing Orange II and Phosphate Solution to act on Iron Gel for a period of six months

pH of dye bath Jan. 1	pH of dye bath July 3	Mgm ads. per gm. dry gel.			
		Dye ads. Jan. 1	Dye ads. July 3	PO ₄ ads. Jan. 1	PO ₄ ads. July 3
5.02	5.46	00	00	232.3	219.6
5.27	5.69	00	00	229.4	238.7
5.66	5.87	00	00	202.7	206.8
5.86	5.95	00	00	191.0	207.3
5.95	6.07	00	00	187.1	171.7
5.71	6.07	00	00	146.3	164.0

The data show that there was no adsorption of dye under these conditions even after being in the presence of the gel for a period of six months. The phosphate adsorption changed only very slightly and the pH shows a correspondingly slight change. It was concluded then that the reason for phosphate cutting out the adsorption was not to be found in its effect upon the dye in the solution.

On the basis of the other idea mentioned above that the phosphate decreased the adsorption of acid dyes because of its effect upon the gel, it was thought possible that the phosphate might be adsorbed on the surface of the gel and thus prevent the gel reacting with the dye.

In order to determine this it was decided to run an experiment in which the gel would be allowed to adsorb the phosphate from the solution before adding the dye. If no adsorption took place it was thought it might be concluded that the phosphate coated the gel in such a way as to prevent its reacting with the dye.

.5 gram of gel and 100 cc. of potassium dihydrogen phosphate was boiled for two hours, then shaken for three days in a mechanical shaker. 25 cc. of the solution was then removed and tested for phosphates. Then 100 cc. of a one per cent dye solution were added and the mixture again boiled and shaken the same as before. The following results were obtained:

FIG. 3

The Relation between the Amount of PO₄ adsorbed and the Amount present in a Bath of Orange II Dye.

TABLE XIII

The Effect of Iron Gel adsorbing all the Phosphate from the Solution first, then adding Orange II

Final pH of bath	Orig. PO ₄ mgm per gm dry gel	PO ₄ in supernatant liquid before dye added	Dye ads	Mgm PO ₄ ads. per gm. dry gel in final bath
5.53	63.7	none	∞	59.4
5.73	127.4	trace	∞	105.4
5.75	190.1	quantity	∞	126.8
5.86	254.8	quantity	∞	154.7
5.27	63.9	none	∞	59.7

It will be noted that there was no dye adsorbed even when there was no phosphate in the supernatant liquid when the dye was added. The data show, though, that some of the adsorbed phosphate was released to the solution after the dye was added. This might have been expected, since in Table XI it was shown that in the presence of Orange II the amount of phosphate adsorbed is proportional to the concentration of the solution. Hence when the solution was diluted with the dye we would expect some of the phosphate to be released. This point is illustrated in Fig. 3.

Since some phosphate was released to the solution this experiment does not prove conclusively its original purpose. It does show, however, that the dye will not replace the adsorbed phosphate on the gel. It then became important to know whether, if the dye was adsorbed first, the phosphate would displace it. In order to determine this the following experiment was performed.

150 cc. of a 0.75 per cent solution of Orange II was boiled with the gel for two hours and samples were removed for analysis. 100 cc. of 0.05 N KH_2PO_4 were then added to each solution. This was shaken for three days to attain equilibrium. The pH of the original dye solutions was varied by adding sulphuric acid and sodium hydroxide. The results of this experiment are given in Tables XIV and XV.

TABLE XIV

The Effect of allowing Aluminum Gel to adsorb Orange II first then adding Potassium Acid Phosphate to the Solution

pH after dye ads.	pH of final bath	Mgm. adsorbed per gm. dry gel			PO_4 ads.
		dye ads. before salt added	dye ads. after salt added	dye released	
5.2	4.8	439.4	119.5	373.9	150.7
5.3	4.9	311.1	24.3	286.8	119.1
5.56	5.2	67.0	15.0	52.0	86.9

TABLE XV

The Effect of allowing Iron Gel to adsorb Orange II first then adding Potassium Acid Phosphate to the Solution

pH after dye ads.	pH of final bath	Mgm adsorbed per gm. dry gel.			PO_4 ads
		dye ads. before salt added	dye ads. after salt added	dye released	
5.05	4.56	407.6	24.4	383.2	166.0
5.11	5.42	245.7	21.6	224.7	141.0
5.48	5.69	9.7	2.0	7.7	114.4
5.49	5.65	9.7	2.0	7.7	120.0

The data show that a very high percentage of the dye is displaced by the phosphate. At first thought it would seem that if this were chemical replacement one equivalent of dye should be replaced by one equivalent of phosphate. These values were calculated and not found to agree in any case. This is as it should be for undoubtedly some of the dye was released on dilution of the solution. Or in other words some of the dye compound already formed is dissolved on the addition of the phosphate solution.

The data presented thus far seem to show that the effectiveness of the phosphate in reducing the adsorption of the dye is due to its effect upon the gel. The thought was then advanced that the phosphate covered the exterior

surface with an insoluble phosphate and did not leave any ferric hydroxide exposed to react with the acid of the dye. It is well known that iron and aluminum gels are precipitated in very large particles, and just as the reaction of sulphuric acid on lead is stopped by lead sulfate, here the reaction may be prevented by the formation of iron phosphate on the surface of the gel. If this concept is true we should be able to increase the adsorption of a salt by taking these larger particles of gel and breaking them apart so as to expose new surfaces.

In order to prove this point samples of iron and aluminum gels were allowed to reach a maximum adsorption with potassium acid phosphate. The gel was then removed and ground thoroughly in a mortar for ten minutes; it was then returned to the solution and placed in the mechanical shaker again. Samples were removed, before and after grinding the gel, for analysis. The pH of the solutions was varied by adding potassium hydroxide. 1.05 grams of gel (90 percent Fe_2O_3 and 74.5 percent Al_2O_3 respectively) were used with 200 cc. of 0.05 N KH_2PO_4 .

TABLE XVI
The Effect of Further Subdivision of the Particle of Aluminum Gel

pH of original salt solutions	pH of bath before grinding	pH after grinding	Mgm. PO_4 ads. per gm dry gel		
			Before grinding	After grinding	Increase
4.683	7.168	7.405	138.4	147.7	9.3
5.799	7.328	7.422	135.6	143.3	7.6
6.287	7.532	7.641	127.6	132.5	4.9
7.084	8.081	8.182	94.4	97.1	2.7
10.718	9.417	9.552	41.1	46.4	5.4

TABLE XVII
The Effect of Further Subdivision of the Particle of Iron Gel

pH of original salt solutions	pH of bath before grinding	pH after grinding	Mgm. PO_4 ads. per gm dry gel		
			Before grinding	After grinding	Increase
4.683	7.151	7.354	166.2	171.5	5.3
5.799	7.303	7.439	163.4	166.1	2.7
6.289	7.557	7.624	154.2	160.7	5.5
7.084	8.098	8.149	121.2	126.0	4.8
10.718	8.706	9.028	58.7	68.8	10.1

The difference in pH between the first and second column does not give the pH change corresponding to the phosphate adsorbed because quite a bit of water was added with the gel. In a total of 48.3 grams of gel plus water there was 47.3 grams of water. With the iron gel in the above experiment even after filtering there was considerable colloidal ferric phosphate in the solution. For the phosphate determination this was removed by saturating the solution with ammonium nitrate which precipitated the colloid. On filtering, the solution was perfectly clear.

The data given in the two preceding tables are presented in Fig. 4.

From these curves it is seen readily that there was quite a definite increase in the adsorption of phosphates by both iron and aluminum gels when new surfaces were exposed by crushing the gel particle. This seems to show that the surface of the gel, when maximum adsorption is reached, is coated with a definite film of phosphate which is impervious to more phosphate or dye under the existing conditions. But when one of these phosphate-coated particles is broken and a new surface exposed, more of the phosphate can be taken up

FIG. 4

The Effect of Further Subdivision of the Particles of Gel on Adsorption of Phosphates

from the solution. This might appear to be then the explanation of the fact that phosphates cut out the adsorption of an acid dye by iron gel. If the layer of phosphate formed cannot be penetrated by additional phosphate from phosphoric acid, then it is reasonable to suppose that the dye cannot penetrate the film. But in experiments following this where less phosphate was used and was still effective in preventing the adsorption of the dye, it is hardly conceivable that there is a sufficient amount of the phosphate radical present to cover the whole surface of the gel. These data, however, certainly seem to explain the always troubling assertion that there is apparently never a definite chemical equivalent relationship between the amount of material adsorbed and the amount of gel present. All of the preceding data were recalculated on the basis that the dry gel was 74.5 per cent Al_2O_3 and 90 per cent Fe_2O_3 respectively and no definite chemical combining ratios were found between the dye or salt adsorbed and the iron or aluminum present as gels. None should be expected according to the data presented in Tables XV and XVI because at all times there might be quite a large score of aluminum hydroxide or iron hydroxide within the gel particle that never comes in contact with the solution and hence cannot be acted upon.

In all of the data presented, the adsorption of the dye in phosphoric acid has been compared to the adsorption in sulphuric acid. In order to have a comparison of the effects of the ions Cl^- , SO_4^{--} and PO_4^{---} upon the ad-

sorption of Orange II, an experiment was run using hydrochloric, sulphuric and phosphoric acids of the same pH values to dissolve the dye, and iron, aluminum and chromium gels as adsorbing mediums. The same amounts of gel and the same percentage dye solution (0.5 per cent) were used in each case. The results are given in grams of dye adsorbed per gram of dry gel. The gel in this state in the case of iron is 90 per cent Fe_2O_3 , that of aluminum 74.5 per cent Al_2O_3 and chromium 70.4 per cent Cr_2O_3 .

FIG. 5

Adsorption of Orange II by Iron Gel in the presence of HCl , H_2SO_4 and H_3PO_4 .

TABLE XVIII

The Adsorption of Orange II by Iron Gel in the Presence of three different acids under the same pH

pH of acid sol. before dye added	Mgm. of dye adsorbed per gm of dry gel		
	HCl	H ₂ SO ₄	H ₃ PO ₄
2.95	8	8	00
2.66	28	15	00
2.33	143	138	00
2.01	440	417	30
1.94	540	500	102

It is shown here that in their adsorption effects with iron gel, HCl and H_2SO_4 are very much alike and H_3PO_4 has cut out the adsorption entirely except at a very low pH. Fig. 5 shows these data plotted. The results with chromium gel are very similar; these are shown in the following table and in Fig. 6.

It is apparent that hydrochloric and sulphuric acids have almost the same effect again except at a very low pH, and phosphoric acid has very greatly reduced the adsorption. The adsorption in the presence of phosphoric acid passes through a minimum. This result is explained in the theory of this reaction which is developed in the latter part of this paper. With aluminum gel the results are similar.

TABLE XIX

The Adsorption of Orange II by Chromium Gel in the Presence of three different acids under the same pH

pH of acid sol. before dye added	Mgm. of dye ads. per gm. of dry gel.		
	HCl	H ₂ SO ₄	H ₃ PO ₄
2.95	24	24	5
2.66	41	35	4
2.33	155	150	00
2.01	475	346	15
1.94	500	390	88

FIG. 6

Adsorption of Orange II by Chromium Gel in the presence of HCl, H₂SO₄, and H₃PO₄.

TABLE XX

The Adsorption of Orange II by Aluminum Gel in the Presence of three different acids under the same pH

pH of acids sol. before dye added	Mgm of dye ads. per gm. of dry gel.		
	HCl	H ₂ SO ₄	H ₃ PO ₄
2.95	90	95	15
2.66	95	96	1
2.33	222	215	25
2.01	560	540	160
1.94	650	620	363

These results are brought out more clearly in Fig. 7. Here again hydrochloric acid seems to offer the best adsorption medium, with sulphuric acid very nearly equal to it and with phosphoric acid there is very little adsorption at all. At a very low pH the amount of dye adsorbed with phosphoric acid present increases very rapidly.

Since the control of the pH has been shown to be a very important factor it was carefully followed in all the stages of the above experiment. The results are given separately for each acid.

When the gel was added to the dye solutions it was mixed with a considerable quantity of water, (47 gms. water plus 1 gram gel). The dilution and the pH of this water had an effect upon the final pH of the bath, but since this was constant in every case it does not enter into the comparison of the effects of the acids. The water with iron gel had a pH of 7.5, that with aluminum 8.36 and with chromium 8.35.

FIG. 7

Adsorption of Orange II by Aluminum Gel in the Presence of HCl, H₂SO₄ and H₃PO₄.

TABLE XXI

The pH Changes during the Adsorption of Orange II in the Presence of HCl

pH of original acid solution before dye added	pH of solution after adding 1 gm of dye to 200 cc sol	pH of bath after equilibrium was reached		
		Al gel	Cr gel	Fe gel
2.95	6.4	6.63	6.91	6.74
2.66	6.0	5.85	6.93	6.34
2.33	x	5.48	6.27	6.12
1.96	x	5.24	5.85	5.10
1.65	x	3.82	2.47	—

In the solutions marked x the pH could not be taken due to the dye precipitating out on the electrode.

TABLE XXI

The pH Changes during the Adsorption of Orange II in the Presence of Sulphuric Acid.

pH of original acid solution before dye added	pH of solution after adding 1 gm of dye to 200 cc sol.	pH of bath after equilibrium was reached		
		Al gel	Cr gel	Fe gel
2.98	6.4	7.12	7.14	6.30
2.69	6.3	6.71	7.13	5.85
2.38	x	6.08	6.40	5.48
2.01	x	—	5.58	4.94
1.79	x	3.82	4.72	—

TABLE XXII

The pH Changes during the Adsorption of Orange II in the Presence of Phosphoric Acid

pH of original acid solution before dye added	pH after adding 1 gm dye to 200 cc solution	pH of adsorption bath after equilibrium was reached		
		Al gel	Cr gel	Fe gel
3.29	6.66	7.40	7.20	6.47
3.01	6.59	7.13	7.10	6.32
2.74	4.9	7.05	7.00	6.28
2.42	x	7.46	6.10	6.20
2.18	x	5.10	5.88	4.81
1.94	x	3.20	2.57	2.08

The increase in pH of the solution on mixing the dye with the acid is due to the formation of the acid dye. It was the formation of this acid dye that made it impossible to determine the pH of the solutions marked x, for when this material is present in large quantities it precipitates on the electrode.

It will be noticed in the above data that when the final pH of the bath was in general below 6.5 with hydrochloric and sulphuric acids quite a large amount of dye was adsorbed. This point varies, of course, with the different gels. But with phosphoric acid before any quantity of adsorption could be obtained the final pH of the bath was lowered to 3.2 for aluminum gel, 2.57 for chromium gel and 2.07 for iron gel.

A few drops of chromium, aluminum, and ferric chlorides were added to the respective phosphoric acid dye baths which had given little or no adsorption. A precipitate of the metal dye compound immediately resulted. This seemed to indicate that one of the conditions necessary to get the dye removed or adsorbed was to have the metal present in an ionizable compound. Had the ions been present before, adsorption would have resulted. At almost any pH value when sulphuric or hydrochloric acid is in the presence of aluminum, iron, or chromium gel, metallic ions will be liberated because of the formation of a soluble sulfate or chloride. With phosphoric acid reacting with the gel, aluminum, iron or chromium phosphate would form, all of which are relatively insoluble except in more concentrated acid solutions. If this theory is true, that the liberation of the metallic ion is necessary in order for it to react with the dye and form the metal-dye compound, then we should find, at the pH values where adsorption was obtained with phosphoric acid, that iron phosphate is soluble and will yield ferric ions in solution. In order to determine this the following experiment was performed.

Ferric phosphate was prepared by treating potassium dihydrogen phosphate with ferric chloride. A white flocculent precipitate was obtained which became curdy on boiling. To equal amounts of this were added varying amounts of .2N phosphoric acid. This was boiled and let stand for a few hours. In some of the tubes it could be seen that some of the ferric phosphate had dissolved, but some white precipitate still remained in all of them. The pH values of the solutions were determined and they were tested for ferric

ions with potassium sulfo-cyanate. At a pH of 6.88 no ferric ions were present. At 2.40 there was a faint test for ferric ions, lower than this at pH 2.077 and 2.029 the number of ions in solution increased greatly. This can be tested qualitatively by adding KCNS to ferric chloride and then adding Na_2HPO_4 . Under these conditions the color will disappear. If phosphoric acid is added, the characteristic red color of ferric ions will reappear due to the ferric phosphate which was first formed dissolving again.

In order to confirm this and have conditions exactly the same as in the dye adsorption experiment, iron gel was mixed with phosphoric acid solutions of various concentrations and subjected to the same conditions under which the adsorption of the dye was carried out. Results were obtained confirming those given above. With solutions of pH above 4.00 no ferric ions were found in solution. Below this the lower the pH the more ions there were present.

Aluminum phosphate was prepared by treating a solution of potassium monohydrogen phosphate with aluminum chloride. This was treated in the same manner as the iron. A total of seven solutions were used. In these the number of aluminum ions present seemed to pass through a minimum at pH of 5.6 above this number of ions present increased and below this the lower the pH the greater was the number of ions present. It is believed that this is due to the amphoteric nature of the aluminum. Referring back to Table XX and Table XXIII we find that the amount of Orange II adsorbed passes through a minimum when the final pH of the bath corresponds very closely to this.

Chromium phosphate was prepared in exactly the same manner as iron phosphate and a similar experiment tried. At a pH of 6.0 there was a trace of chromium ions in solution but they did not appear in an appreciable amount until a pH of 2.8 was reached, lower than this the amount present increased rapidly. Referring back to Tables XIX and XXIII, it will be noticed that with chromium gel a small amount of dye was adsorbed in the presence of phosphoric acid at a pH of 5.6 but the first adsorption of a large amount of dye was at a pH of 2.6.

In every case the adsorption of the dye checks very closely with the amount of metal passing into solution in the form of ions. Here we believe is the explanation of the effect of the phosphate radical on the adsorption of an acid dye. The amount of dye removed depends upon the number of metal-ions there are in solution to react and form the metal-dye compound. Hydrochloric and sulphuric acids react with the gels, form soluble salts and furnish the metal ions to the solution. The more acid there is present the more metal ions there will be in solution, hence we find the greater adsorption of the dye at the lower pH. With phosphoric acid, however, reacting with the gel relatively insoluble salts are formed and no ions are furnished to the solution until the acidity is of such concentration that it dissolves these salts. As was shown the solubility of these phosphates vary, iron being the most insoluble.

The series of reactions through which this process of dyeing the mordant, goes are thought to be as follows: For simplicity let x represent the dye radical.

Gordon and Marker have shown that the compound formed by the dye with the metals is AlX_3 , FeX_3 and CrX_3 . Aluminum gel and hydrochloric acid are used as an illustration.

That this reaction takes place and forms the weaker acid HX is shown by the great increase in pH when Orange II is added to an acid solution. Data illustrating this are given in Tables XXI-XXIII.

This reaction was proven by taking various mixtures of the acid and gel and testing for the ions formed.

The salt AlX_3 is relatively insoluble and is thus removed from the field of action. This reaction has been illustrated by adding crystals of aluminum, iron and chromium chlorides to a water solution of Orange II. In every case an immediate precipitate results. It is believed that most of the metal-dye compound is formed by this reaction. A small fraction may be formed by the reaction of the dye acid and the gel but this is highly improbable since the base is extremely weak and the acid is relatively weak.

If this is the essential reaction then phosphoric acid should assist the dyeing just as effectively as sulphuric or hydrochloric acids, because with phosphoric acid the dye acid, HX , is formed just as in the other two cases as the data in Table XXIII show.

If no acid is present some small amount of the metal dye salt may be formed due to the slight ionization of aluminum hydroxide.

There is also the possibility that some of the dye acid formed reacts with the $AlCl_3$ formed by reaction (2).

However the evidence seems to indicate that the essential reaction for the formation of the metal-dye compound is reaction (3). On the basis of this we can explain the very sudden increases in adsorption of Orange II at a low pH which were noted by Gordon and Marker. They found that the adsorption of Orange II increased steadily until a certain relatively low pH was reached; at this point further addition of acid caused very rapid increase in the adsorption. We explain this point by claiming that it occurs at the hydrogen ion concentration where enough acid has been added to shift reaction (1) as far as possible to the right. Any more acid added would react directly with the gel and proceed through reactions (2) and (3).

With sulphuric acid the reactions given above would be of the same nature as with hydrochloric acid.

With phosphoric acid, reaction (1) is the same as with hydrochloric. But in reaction (2) there would be formed either $\text{Al}(\text{H}_2\text{PO}_4)_3$, $\text{Al}_2(\text{HPO}_4)_3$ or AlPO_4 . Since there is a large amount of gel present and only a small amount of acid it is believed that the major compound would be AlPO_4 . This compound was shown to be relatively insoluble and corresponding salts of chromium and iron still more insoluble. The formation of this insoluble product in reaction (2) would prevent reaction (3) from taking place and hence would prevent adsorption, by this reaction taking place. This is borne out by the experimental data given above. Aluminum phosphate was found to be slightly soluble under all the conditions used and some adsorption of the dye was found in all cases. The pH values at which chromium gel gave adsorption of dye in the presence of phosphate were found to correspond with those at which chromium phosphate yielded chromium ions to the solution. And finally, it was found that iron gel in the presence of phosphates adsorbed dye at only a very low pH value. This corresponded to the point at which iron phosphate yielded ferric ions to the solution.

The experimental facts seem to indicate that in order to have an acid dye removed from solution by a gel, in any large quantity, the metal ion must be free. This is accomplished by adding sulphuric or hydrochloric acids which react with the gels to form soluble salts. Phosphates decrease the adsorption because of the formation of difficultly soluble salts with the gels.

Summary of Experimental Results

I. The presence of .05 normal potassium dihydrogen phosphate greatly decreased the adsorption of an acid dye with aluminum gel and iron gel.

II. Using H_3PO_4 solution in the dye bath the adsorption of Orange II was very much decreased with aluminum gel and cut out entirely with iron gel except at a very low pH.

III. Iron gel was allowed to adsorb all of the phosphate from .01N KH_2PO_4 and .012N H_3PO_4 , then Orange II dye was added. No dye was adsorbed.

IV. Iron and aluminum gels were allowed to adsorb dye from a .5 per cent solution of Orange II at pH values varied with KOH and H_2SO_4 . Potassium acid phosphate was then added. Most of the dye was released and the phosphate adsorbed.

V. Iron gel was allowed to remain with dye solutions in .05N potassium acid phosphate for a period of six months. Even at the end of this period no dye was adsorbed.

VI. Iron and aluminum gels were allowed to reach adsorption equilibrium with .05N KH_2PO_4 . The gels were removed, and ground in a mortar then put back into the solutions. There was an increase in adsorption in all solutions used.

VII. The adsorption of Orange II by iron, aluminum, and chromium gels was tried with the following results.

Aluminum gel: High adsorption of dye with HCl and H₂SO₄.
Low adsorption of dye with H₃PO₄.

Chromium gel: High adsorption of dye with HCl and H₂SO₄.
Very low adsorption of dye with H₃PO₄.

Iron gel: High adsorption of dye with HCl and H₂SO₄.
No adsorption of dye with H₃PO₄ except at a very low pH value.

The order of increasing adsorptive power for Orange II is: iron, chromium, aluminum.

VIII. In cases where phosphate is adsorbed from solutions having varying phosphate concentrations the amount adsorbed in the presence of Orange II dye is a straight line function of the amount present.

IX. Chromium, iron, and aluminum as chlorides when mixed with solutions of the sodium salt of Orange II give an immediate precipitate of the respective metal-dye compound.

X. Chromium, iron, and aluminum chlorides dropped into the H₃PO₄ solution from which no dye was adsorbed gave immediate precipitates of the metal-dye compound.

XI. The solubility of aluminum phosphate in phosphate solutions of various hydrogen ion concentrations was found to coincide with the adsorption curve of Orange II by aluminum gel in phosphate solutions.

Iron phosphate was found to be soluble at the same pH at which the iron gel adsorbed Orange II.

Chromium phosphate was also found to be soluble in phosphate solutions at the same pH where adsorption of Orange II was found.

Conclusions

The decrease in the adsorption of an acid dye, Orange II, by iron, aluminum and chromium gels (mordants) in the presence of phosphates is not due to any effect of the phosphate radical upon the dye or the solution. It is due to the phosphate forming a relatively insoluble compound with the gels, hence not furnishing any metal ions to react with the dye and form the metal-dye compound which is the cause of adsorption. At high hydrogen ion concentration adsorption takes place because the metal phosphate becomes soluble. The reactions supposed to take place during the adsorption of an acid dye Orange II by an inorganic gel are best expressed in the following equations:

Let x represent the dye radical and using iron gel with a hydrochloric acid solution of the dye for an example:—

It is postulated that most of the adsorption is due to reaction (3). Some little may be due to reactions (4) and (5).

Sulphuric acid acts very similar to hydrochloric in these reactions.

Phosphoric acid acts in reaction (1) similar to hydrochloric. In reaction (2) phosphoric acid forms an insoluble iron phosphate thus preventing reaction (3) from taking place and no adsorption results unless the solution is made sufficiently acid to dissolve the iron phosphate.

Aluminum and chromium gels act similar to iron.

THE EFFECT OF NEUTRAL SALTS ON CERTAIN CATALYTIC DECOMPOSITIONS*

BY C. CLEMENT FRENCH

Much experimental material is available on the velocity of reaction of compounds subject to catalytic decomposition by the hydrogen ion and on the effect of neutral salts in such reactions. Similar studies in cases where the catalyst is the hydroxyl or other ion are not so numerous. With the idea of contributing more experimental data of a comparatively high degree of accuracy to the field of neutral salt action in homogeneous catalysis, this work has been undertaken.

Two reactions were investigated: 1. The decomposition of hydrogen peroxide, catalyzed by the iodine ion. 2. The decomposition of nitroso-triacetone-amine, catalyzed by the hydroxyl ion, each in the presence of various neutral salts.

It is well known that hydrogen peroxide is completely decomposed by solutions of soluble acid-free iodides, the concentration of the iodide or iodine ion remaining constant during the reaction. Walton,¹ from a careful study of the velocity of decomposition of hydrogen peroxide with sodium, potassium and ammonium iodides, has shown the reaction to be of the first order and complete. He further showed that up to concentration of the iodides of about 0.04 N, the reaction appeared to be proportional to the concentration of the iodide ion, and is independent of the concentration of the water. Consequently, this is a reaction which careful study has shown to be an ionic catalysis and in which the effect of neutral salts could be studied on catalysis by an ion other than the hydrogen ion.

Walton has reported only one result on the reaction velocity with each of the following salts: potassium chloride, sodium chloride, potassium sulphate, sodium sulphate, potassium nitrate and potassium chlorate, in a 0.0313 N potassium iodide solution. The effect of the chlorate was negligible, potassium sulphate decreased the velocity slightly while the other salts increased the velocity.

Harned² has studied the effect upon the velocity of this reaction of the addition of potassium, sodium and lithium chlorides, up to concentrations of 3 N, in solutions of 0.02 N and 0.03 N potassium iodide.

Nitroso-triacetone-amine in the presence of the hydroxyl ion changes into phorone, nitrogen and water according to the following equation:

* Contribution from the John Harrison Laboratory of Chemistry of the University of Pennsylvania.

¹ Walton: *Z. physik. Chem.*, **47**, 185 (1904).

² Harned: *J. Am. Chem. Soc.*, **40**, 1461 (1918).

This reaction was discovered by Heintz¹ and has been carefully studied by F. Francis² and his co-workers, who showed it to be a simple first order reaction, catalyzed by the hydroxyl ion. At hydroxyl ion concentrations above 0.05 N, the reaction mechanism appears to change since the monomolecular law which holds at lower hydroxyl ion concentrations fails to hold at these higher catalyst concentrations. More recently, this reaction has been investigated by Brönsted and King³ in connection with secondary kinetic salt effect, and by Kilpatrick⁴ in studying catalysis in buffer solutions. Brönsted and King report the effect of sodium chloride in concentrations up to 0.2 N on the velocity at 15°C., and Kilpatrick the effect of sodium chloride up to about the same concentration on the velocity at various temperatures.

Experimental Methods

Materials:—The action of the following salts was investigated:

1. Chlorides of potassium, sodium, lithium, barium, strontium, calcium and magnesium.
2. Sulphates of potassium, sodium, lithium and magnesium.
3. Bromides of potassium and sodium.
4. Potassium iodide.

All salts were of the best grade of analyzed chemicals obtainable. In all cases where there was no danger of decomposition on heating, the salts were ground and dried by careful heating. After drying, all salts were tested for neutrality. A sample of the salt was dissolved in 50 cc. of distilled water and a few drops of indicator added. The addition of a drop of dilute sodium hydroxide solution in every case gave a sharp color change.

The chlorides of lithium, magnesium and calcium were used in solution. The solutions of the first two were made by adding the salts to redistilled water in quantity nearly sufficient to make a saturated solution at room temperature. It was found that this method could not be employed with calcium chloride. In this case, the analyzed salt was added to redistilled water almost to saturation. The solution was then filtered and a slight excess of hydrochloric acid added to overcome the original alkaline reaction of the solution. Precipitated calcium carbonate was then added in excess to the boiling solution, and the solution filtered while warm. After standing over night, the crystals of calcium chloride were filtered, sucked free of mother liquor, and dissolved in redistilled water, making the final solution as used. The solutions were analyzed by precipitating the chloride ion with silver ion in acid solution, and weighing the silver chloride. As a check, the specific gravity of each solution was determined with the Westphal Balance, and the salt content determined from the Tables of Landolt-Börnstein.

A 3 per cent solution of hydrogen peroxide was used. It contained a trace of acid, but as the maximum concentration used was 4 cc. of this solution in

¹ Heintz: *Ann.* **187**, 250 (1877).

² Clibbens and Francis: *J. Chem. Soc.*, **101**, 2358 (1912); Francis and Geake: **103**, 1722 (1913); Francis, Geake and Roche: **107**, 1651 (1915).

³ Brönsted and King: *J. Am. Chem. Soc.*, **47**, 2523 (1925).

⁴ Kilpatrick: *J. Am. Chem. Soc.*, **48**, 2091 (1926).

100 cc. total volume of solution, the amount of acid present in the final solution was negligible. That this was true was shown by the fact that neutral potassium iodide liberated but a trace of iodine when added to it.

Nitroso-triacetone-amine as purchased was recrystallized by dissolving in the minimum of alcohol at 50°C and precipitating by the addition of a little warm water. The product thus obtained was pressed dry. It was a pale yellow solid, melting at 72°C.

Standard 0.1 N potassium hydroxide solution was made by diluting a nearly saturated solution of potassium hydroxide from which the carbonate had been removed by a slight excess of barium hydroxide. While the standard potassium hydroxide solution contained traces of barium hydroxide, the amount present was almost beyond detection, as in the original solution only a trace was present. The standard alkali solution was analyzed by titration with 0.1 N hydrochloric acid solution which had been standardized gravimetrically. The alkali solution was preserved in a large bottle fitted with soda-lime tubes.

Apparatus:—All measurements were made at $25 \pm 0.01^\circ\text{C}$. The thermostat was rather large, containing over 400 liters of water. The heating was controlled by a large grid-shaped thermo-regulator, filled with mercury and having a surface of over 2000 sq. cm. Variations in the temperature could not be detected on a Beckmann thermometer for periods of several days, so the deviation from 25° during a measurement was probably less than 0.01°C .

The decomposition of hydrogen peroxide is accompanied by the evolution of oxygen and that of nitroso-triacetone-amine by the evolution of nitrogen. Hence the velocity of each of these reactions can be determined by measuring the volume of the gas evolved at various time intervals. Walton and Francis¹ both obtained sufficient agitation by rapid shaking of the reaction vessel. Brönsted and King² also used this method. Harned, and more recently Kilpatrick,³ used the stirring method for the agitation of the solution. In either case, the important point is "to agitate the solution to such an extent that the gas is registered on the volume-measuring apparatus as soon as it is produced in the solution."⁴ In this work, the solution was agitated by a rapidly revolving glass stirrer, sealed off from the outside by a mercury seal.

The reaction vessel is shown in Fig. 1. A is a 500 cc. Pyrex Erlenmeyer flask, in the bottom of which three openings have been made. The tube B, sealed in through the first opening, is a 2 mm. capillary through which water or salt solution was added. The upper end of this tube was connected by a ground glass slip-on joint to the filling cup C. The tube D, sealed into the flask through the trap E, led to the gas volume burette. The latter was similar to that used by Walton,⁵ and contained water. The gas burette was sur-

rounded by a water jacket, maintained at a temperature of 25° by pumping water from the thermostat through it. To the flask at the third opening was sealed the tube F, of a diameter sufficient to permit the withdrawing of the stirrer. The larger concentric tube G, forming a trough for the mercury seal, was sealed to the tube F. To the stirrer shaft was sealed the tube, H-H, of a proper diameter to dip down into the mercury reservoir as shown. The stirrer shaft J revolved in two close fitting brass tubes, K-K, which in turn were clamped firmly in position. The pulley L was securely fastened to the glass tubing M, which in turn was sealed to the stirrer shaft. Since the stirrer was rotated at a high rate of speed, it was necessary that the shaft be carefully centered to prevent splashing of the mercury and consequent gas leakage.

FIG. 1

The following procedure was adopted in making the measurements with hydrogen peroxide. The reaction vessel was first carefully washed with water and alcohol, and dried in a current of air. The filling cup C was then attached and secured by small rubber bands fastened over the glass hooks at the joint. Then a weighed quantity of salt was added through the tube F, or if a salt solution was being used, through the filling cup. Then to this was added the calculated quantity of water, together with 4 cc. of the 3 per cent hydrogen peroxide solution. The apparatus was placed in the thermostat bath and the contents of the vessel stirred until the salt had

dissolved and the solution had come to the temperature of the bath. The stirrer was then removed and the proper quantity of solid potassium iodide, weighed out and wrapped in a small piece of filter paper, was dropped in. The stirrer was replaced, the gas outlet tube D fastened to the gas burette by a piece of tight-fitting rubber tubing and mercury added to make the seal. The stirrer was then rotated and when the potassium iodide had dissolved and a steady evolution of oxygen was secured, readings of the gas burette were begun. Readings were taken at convenient intervals until the decomposition was over 75 per cent complete. After that the reaction was allowed to proceed to completion and the final volume recorded.

In the work with nitroso-triacetone-amine, essentially the same procedure was followed, 0.15 grams of the nitrosamine, together with the calculated quantity of water and salt or standard salt solution, were placed in the reaction vessel. The whole was then stirred in the thermostat until solution was obtained at the temperature of the bath. As the nitrosamine dissolves very slowly in water at 25° , care had to be taken that sufficient time was allowed for its complete solution. When this was accomplished, the standard alkali solution was added through the filling cup, the delivery tube attached to the

gas burette as above and readings begun when about 2 cc. of nitrogen had been evolved. When sufficient readings had been obtained, the stirrer was stopped because of the long time necessary for the completion of the reaction. After standing for over 24 hours, the solution was again stirred for 30 minutes and the final volume read on the gas burette. Readings of the volume were made to 0.05 cc. In the work with hydrogen peroxide, a total volume of 100 cc. was used: with the nitroso-triacetone-amine, 200 cc.

Effect of Various Salts on the Decomposition of Hydrogen Peroxides, catalyzed by the Iodine Ion

A number of preliminary experiments were necessary. Hydrogen peroxide solution is slowly decomposed by sharp glass edges and by ground glass. In order to determine the extent of this decomposition, as well as to make sure

that the apparatus under the conditions of the experiment was gas-tight, preliminary runs were made with the hydrogen peroxide present in the vessel, but without the catalyst. It was also necessary to determine whether the filter paper in which the potassium iodide was added, had any effect on the rate of decomposition. Finally, runs were made in the absence of potassium iodide with each of the salts whose effect was to be studied, in order to ascertain whether they alone produced an appreciable evolution of oxygen; and to determine the rate of such evolution if sufficient to make a future correction necessary. These results are summarized in Table I.

Experiments A and B in the above table are taken from the data of Harned¹ and are inserted here to emphasize the relation between the various salts and the magnitude of the effect produced by them in the absence of potassium iodide. The above results show without question that any decomposition due to the apparatus, stirrer or filter paper is negligible. The presence of concentrated solutions of bromides and chlorides does cause a slow decomposition of hydrogen peroxide. Engler and Nasse and Schöne² have reported that concentrated chloride and bromide solutions slowly decompose hydrogen peroxide, and that of the two the action of the bromide is the more vigorous. The results shown above confirm this. The magnitude of the corrections will be considered later.

The velocity constants are calculated according to the equation of the first order,

$$K = 2.303/t \log_{10}(V_{\infty} - V_0)/(V_{\infty} - V_t)$$

where K is the velocity constant, t the time in minutes, V_{∞} the final reading of the gas burette, V_0 the reading at time $t = 0$, and V_t the reading at any time t . In most cases, the calculation of K in this manner gave values of good constancy. In a few cases, the first one or two values of K showed a regular change, and in these cases the values were discarded and the next reading taken as the starting point. This recalculation in most cases gave a series of values for K of a satisfactory degree of constancy. If not, the measurements were repeated with freshly prepared solutions. In Table II, two complete series of constants are given to show the degree of constancy obtainable.

The maximum variation from the mean in the first series is 1.5 per cent, and in the second 1.3 per cent. The maximum variation from the mean in any of the runs giving accepted results was never greater than 2.5 per cent. Duplication of the series with barium, strontium and calcium chlorides, as well as the repetition of various check points with the other salts showed that the mean value of K could be reproduced in two completely different experiments to within 1.5 per cent. This compares favorably with the constancy and reproducibility reported by Francis³ and by Walton⁴ on measurements of this

		Mean K = 0.0532

kind. A further check on the accuracy of the values obtained is found in a comparison of the values for K at a catalyst concentration of 0.02N and in the absence of added salt. While Walton does not report a result for this exact concentration, the value read for it from a curve drawn through K values for concentrations on both sides of 0.02N is 0.0265; Harned¹ reports 0.0275, while the value obtained here is 0.0270. This lies midway between the two other values, and differs from them by about 1.8 per cent, which was found to be about the reproducibility in independent experiments.

Referring now to Table I, it is found that the various neutral salts have very different effects upon hydrogen peroxide in the absence of potassium iodide. The halides have a rapidly decreasing effect in the order iodide, bromide, chloride, while the sulphates show no action. In the case of the

¹ Harned: J. Am. Chem. Soc., 40, 1461 (1918).

chlorides, it is interesting to note that the magnitude of the effect produced in equivalent salt concentrations is quite different with different cations. Since at 25° these decompositions were quite slow, the values obtained for infinity reading of the gas burette would have been of very uncertain quality. Hence

*Mean of two values.

a number of readings were made over a period of three hours or more (only a few of which are listed in Table I) and from these readings, taking a value for the infinity reading such as to give the greatest constancy to the series of K values calculated, the mean value of K for each decomposition was determined. A summary of these results is contained in Table III.

The corrections to the observed values of the rates of decomposition in the presence of potassium iodide and neutral salts would be less than 1 per cent in the cases of barium chloride, strontium chloride and magnesium chloride, hence no correction has been applied in these cases. With sodium and potassium bromides and calcium chlorides, the correction in Table III was used. This was taken as proportional to the salt concentration, since it was found in the pure salt solution that the rate was very nearly proportional to the concentration of salt. Table IV contains the mean corrected values of K. All salt concentrations are in weight normality.

Effect of Various Salts on the Decomposition of Nitrogen-Triacetone-Amine, catalyzed by the Hydroxyl Ion

Brönsted and King¹ have pointed out that carbon dioxide must be excluded from the apparatus and Kilpatrick² worked in an atmosphere of nitrogen, in order to exclude oxygen as well as carbon dioxide, during the course of this reaction. The apparatus as previously described was designed for the hydrogen peroxide reaction, and did not readily permit of operation in an inert gas atmosphere. The purpose of this investigation was not so much to obtain absolute values for the reaction velocity constant as to secure the distribution of the curves caused by the addition of various neutral salts. Recently Åkerlöf³ has measured the velocity of decomposition of diacetone alcohol to acetone in alkali hydroxide-alkali salt solutions. This work affords one of the few exact investigations of a decomposition catalyzed by the hydroxyl ion. It was thought that it would be of interest to compare the distribution of the velocity constant curves for a few salts with each of these reactions, since each is a first order reaction catalyzed by the hydroxyl ion. By working at a temperature lower than that used by Francis,⁴ and at a much lower concentration of hydroxyl ion, the salt effect would be greater for the same salt concentration and consequently the curves for various salts would be more widely distributed.

The error due to any carbon dioxide in the reaction vessel should be fairly constant in all experiments, since the same procedure was followed consistently. The alkali solution was never added until just before the vessel was closed off from the air, and the volume of air space above the liquid was always the same. The results seem to indicate that these assumptions were justified, for quite uniform results were obtained, and the curves for the various salts are reasonably smooth.

² Kilpatrick: *J. Am. Chem. Soc.*, **48**, 2091 (1926).

³ Åkerlöf: *J. Am. Chem. Soc.*, **48**, 3046 (1926).

⁴ Clibbens and Francis: *J. Chem. Soc.*, **101**, 2358 (1912).

One other point regarding the measurements should be mentioned. Due to the slowness of this decomposition in the presence of salts at fairly high concentrations, the quantity of nitrogen evolved between two readings of the gas burette at ten minute intervals often was not more than 1 cc. An error of 0.05 cc., the limit of accurate reading, would make a much greater variation probable in a series of readings than in the case of the hydrogen peroxide series, where from 7 to 8 cc. were collected during the same time. Consequently, for a given series variations of 3 to 4 per cent from the mean value of K were not uncommon. This was also found by Francis,¹ who reported the variation as about 3 per cent. Table V contains the mean values of K .

TABLE V
Hydroxyl Ion Catalysts of Nitroso-Triacetone-Amine in Neutral Salt Solutions

Catalyst 0.014N Potassium Hydroxide. Temperature 25°C.

Values of $K \times 10^4$

N	KCl	NaCl	LiCl	KBr	KI
0.0	143	143	143	143	143
0.5	120	116	105	107	83
1.0	109	100	84	87	57
1.5	98	—	—	80	46
2.0	93	80	54	65	37
2.5	85	—	—	54	27
3.0	80	57	33	47	23

The values for K have been calculated as in the previous work with hydrogen peroxide, using the minute as the unit of time. While no very good agreement was expected, the value of K for 0.014N potassium hydroxide in the absence of neutral salt was compared with the value of Francis. Since Francis worked at 30°, and did not record a value for K at the concentration of catalyst used here, it was necessary to secure a value from his results comparable with the value found above. From a curve of his values at varying potassium hydroxide concentrations at 30°C, the value $K = 0.0250$ at 0.014N catalyst concentration was read off. Kilpatrick² has recently determined the temperature coefficients of this reaction between 20°C and 30°C, using sodium hydroxide as the catalyst. He reports $K_{30}/K_{20} = 2.57$. Assuming that $K_{30}/K_{25} = K_{25}/K_{20}$, K_{30}/K_{25} would equal 1.6. With this value of the temperature coefficient, the value of Francis at 30° becomes $K = 0.0156$ at 25°C. The value obtained here for the same catalyst concentration is $K = 0.0143$, a difference of about 8 per cent, which was rather an unexpectedly close agreement.

In addition to the experiments with the salts listed above, a considerable number of runs were made with sodium, potassium and lithium sulphates. The results obtained were most irregular, in spite of repeated efforts to obtain

¹ Clibbens and Francis: J. Chem. Soc., 101, 2358 (1912).

² Kilpatrick: J. Am. Chem. Soc., 48, 2091 (1926).

values which would fall on a smooth curve. In general, sodium sulphate appeared to cause a slight increase in velocity; potassium sulphate a decrease, but not approaching the magnitude of the salts listed above; and lithium sulphate a decrease in velocity approaching in magnitude that caused by sodium chloride. This irregular action with the alkali sulphates agrees with the observations of Francis¹ on the same salts. He also was unable to secure consistent values.

FIG. 2

Curves for the reaction velocity of the decomposition of hydrogen peroxide in neutral solutions of 0.02 *N* potassium iodide and increasing concentration of various salts.

Dicussion

1. Hydrogen Peroxide Decomposition.

In Fig. 2, the reaction velocity constant *K* is plotted against the normal concentration of added salt, the concentration of potassium iodide being kept constant. The results of Harned² for the alkali chlorides are plotted with dashed lines. It will be noticed that an increase in velocity is obtained with every salt but potassium sulphate, where there is a slight decrease. Walton,³

¹ Cillbrens and Francis: J. Chem. Soc., 101, 2358 (1912).

² Harned: J. Am. Chem. Soc., 40, 1461 (1918).

³ Walton: Z. physik. Chem., 47, 185 (1904).

in the single results reported by him for a few salts, obtained a velocity change in the same direction as is here found. Further, the curves are of the same general form as those obtained by Harned for the alkali chlorides. For a given concentration of salt, his curve for sodium chloride is just below the curve for sodium bromide found here, and his curve for potassium chloride just below the potassium bromide curve found here.

Harned¹ pointed out that the salt effect on the reaction velocity was in the same order as the activity coefficients of the added salts and was of the expected order of magnitude. Recently, Harned and Åkerlöf and Harned and Douglas² have calculated the activity coefficients of all these salts by the equation

$$\log f = - \frac{u\sqrt{\sum c_i z_i^2}}{1 + A\sqrt{\sum c_i z_i^2}} + B\sum c_i z_i^2$$

where f is the activity of the electrolyte divided by its mol fraction, c_i the concentration in mols per 1000 cc. of solvent, and z_i the valence of an ion of the i^{th} kind. The first number on the right is obtained from the theory of Debye and Hückel. u is a universal constant and A is a constant characteristic of each salt but which has nearly the same value for a given type of salt. The constant B is characteristic for each electrolyte and is a measure of the differences in magnitude of the activity coefficients of the electrolytes of a given type. In Table IV are given the values of B for the different salts.

TABLE VI
The Constants of the Linear Salt Effect

Electrolyte	KCl	KBr	NaCl	NaBr	LiCl
B	0.017	0.022	0.028	0.040	0.070
Electrolyte	BaCl ₂	SrCl ₂	CaCl ₂		
B	0.0285	0.030	0.060		
Electrolyte	K ₂ SO ₄	Na ₂ SO ₄	Li ₂ SO ₄		
B	-0.014	-0.005	+0.0087		

The distribution of the results of velocity measurements are in a general way in the order of the B values. Had $\sum c_i z_i^2$ instead of normal salt concentration been plotted against the velocity constants, the curves of barium and strontium chlorides would fall in approximately the order of the B constants. It is interesting to note that potassium sulphate which has a negative B value decreases the velocity constant.

The univalent halides conform well, and the order of the sulphates follows that of the B values. That the situation is very complicated, however, is shown by the distribution of the curves for the alkaline earth chlorides. The

¹ Harned: J. Am. Chem. Soc., 40, 1461 (1918).

² Harned and Åkerlöf: Physik Z., 27, 411 (1926); Harned and Douglas: J. Am. Chem. Soc., 48, 3095 (1926).

*Hückel: Physik. Z., 26, 93 (1925).

B values are in the order barium, strontium and calcium chlorides, while the velocity curves are in the order strontium, calcium, and barium chlorides. When this result was obtained, all these measurements were repeated but no evidence for a re-distribution of curves resulted. Both series of results are included in Table IV and the values plotted are the mean of the two measurements for each point.

FIG. 3

Curves for the reaction velocity of the decomposition of nitrosotriacetone-amine in alkaline solutions of different salts at constant potassium hydroxide concentration of 0.014 *N* and increasing salt concentration.

The neutral salt effect is shown to be very complicated when the above results are contrasted with the hydrogen ion catalysis of ethyl acetate in neutral salt solution. In the latter case, the alkaline earth chlorides are in the order barium, strontium, calcium while the alkali halides are in the order bromide, chloride, the reverse of what is found for the iodide ion catalysis of hydrogen peroxide.

2. Nitroso-triacetone-amine Decomposition.

In Fig. 3, the reaction velocity constant of the decomposition of nitroso-triacetone-amine has been plotted against the normal concentration of salt added. In an accurate study of the decomposition of diacetone alcohol in alkali hydroxide-alkali salt solutions, Åkerlöf¹ found that the order of results was the same as the activity coefficients of the hydroxides in the salt solutions

¹ Åkerlöf: J. Am. Chem. Soc., 48, 3046 (1926).

as determined by Harned, Harned and Swindells and Harned and James.¹ This was nearly always the reverse of the neutral salt effect in hydrogen ion catalysis. Thus, the decrease in velocity constant was greatest in the order potassium chloride, potassium bromide, sodium chloride, sodium bromide, potassium iodide, sodium iodide, and lithium chloride. Although we find the order potassium, sodium, lithium chloride, and potassium chloride, bromide and iodide in agreement with the results of Åkerlöf, the general distribution of the results is considerably different.

To sum up, the distribution of the results is shown to be different in each of the four type reactions discussed. This shows conclusively that no simple explanation will suffice for all and that two factors or more are operative.

The author wishes to express his appreciation to Dr. Herbert S. Harned, at whose suggestion this investigation was carried out, and to Dr. Gösta Åkerlöf, for his helpful advice during the course of the work.

Summary

1. The velocity of decomposition of hydrogen peroxide by neutral potassium iodide and of nitroso-triacetone-amine by potassium hydroxide in a number of different salt solutions has been measured at 25°C with constant catalyst and varying salt concentrations.

2. The complicated nature of the neutral salt effect has been discussed.

THE CATALYTIC DECOMPOSITION OF METHANOL¹

BY DAVID F. SMITH² AND CHARLES O. HAWK³

Introduction

In this paper are presented the results of experiments to determine the nature and effectiveness of various catalytic materials which will decompose methanol into carbon monoxide and hydrogen. The kinetic view of equilibrium in a chemical reaction shows that a catalyst which accelerates the rate of a reaction in one direction must accelerate the reverse reaction rate also. We are therefore assured that a catalyst which decomposes methanol into carbon monoxide and hydrogen will, under thermodynamically suitable conditions, form methanol from these gases. Our experiments thus have a practical interest in that they represent a very simple method for the testing of catalysts for the formation of methanol from water gas, without resorting to the use of costly and troublesome high pressure apparatus.

Approximate thermodynamic data for this reaction have already been published.⁴ These data show that at equilibrium above about 200°C., methanol vapor at one atmosphere is appreciably decomposed into CO and 2H₂; at 300° it is over 96% decomposed. High pressure, of course, favors the reaction in the direction to form methanol. At 300°C. and pressures above 100 atmospheres, practical yields of methanol may be obtained from water gas in the presence of suitable catalysts. In the absence of catalysts, however, methanol vapor remains undecomposed up to temperatures around 800°C.⁵

Although methanol has been produced from water gas on a commercial scale for some time, little information is available on the nature and action of the catalysts used. Brief statements regarding the nature of the catalysts have been made in two or three technical papers on the methanol process. In the patent literature various materials are said to be effective as catalysts. However, there is no information available on the action or relative effectiveness of these catalytic materials or on their preparation and treatment. The aim of the present work is to make available some definite information on the relative effectiveness of catalysts for this reaction and to determine the effect of promoters and method of preparation and treatment.

Experimental Method

Absolute methyl alcohol from a burette at room temperature was passed through a vaporizer consisting of a coil of glass tubing immersed in boiling aniline, and then directly into a glass catalyst tube in an electric furnace. The rate of flow of the methanol was regulated by a capillary stopcock with a V-shaped notch cut in the key. The catalyst extended over but a short distance in the center of the furnace. The temperature was read by means of a thermocouple fastened to the outside of the catalyst tube. The vaporizer was fitted tightly against the furnace tube in order to prevent subsequent condensation of the methanol vapor. The undecomposed methanol was caught and weighed in a coil of tubing immersed in a mixture of carbon dioxide snow and acetone. The gaseous products passed through gas sampling apparatus and a bubbler. Since the rate of gas evolution is, over a small range, approximately independent of rate of passage of methanol over the catalyst, the rate of bubbling of gas immediately furnishes a rough measure of the activity of the catalyst. From the temperature and the known density of the methanol in the burette could be calculated the weight of methanol used. This weight was compared with the weight of methanol caught in the condenser and the fraction decomposed thus determined. The composition of the gaseous decomposition products was determined in most of the experiments.

The catalyst in all cases extended over a length of 8.5 cm. in a glass tube 1.6 cm. in internal diameter. The gross volume of catalyst was thus 17.1 cc. The tube was supported horizontally, the catalyst being held in position by plugs of glass wool. In the earlier experiments the catalyst in the form of a dried cake was broken into uniform pieces just small enough to pass through a glass tube 0.7 cm. in internal diameter. In later experiments the catalyst in the form of a moist paste was passed through a press which produced a cylindrical thread of about 2.8 mm. diameter. This thread, after drying, was cut into pieces about 7 mm. in length. In the latter way catalysts were obtained of fairly uniform surface and porosity. Different preparations of the same catalyst by a uniform method checked fairly well in activity. All catalysts were dried in air at 80° to 100°C. immediately after they were run through the press and were usually subjected to a preliminary reduction at 300°C. by hydrogen before placing them in the catalyst tube, since appreciable shrinkage in volume sometimes occurred in the process.

Preparation of Catalysts

1. Pure commercial chromic anhydride (CrO_3) with a small amount of water was added to high grade commercial zinc oxide. The atomic proportions of Zn:Cr varied from 10:1 to 1:1 as indicated below. The resulting paste, which was ground thoroughly together in a mortar, was pressed into appropriate form for use, dried at 100° and reduced with hydrogen or methyl alcohol vapor at 300°.

2. A solution of sodium chromate was added to a solution of pure zinc nitrate. The precipitate was washed free of nitrate, dried and reduced as above.

3. A solution of sodium carbonate was added to a hot solution of zinc nitrate. The precipitate was washed, dried, placed in a tube heated to 350° , and evacuated until no more carbon dioxide was evolved.

4. A solution of ammonium hydroxide was added to a solution containing zinc and chromium nitrates in the ratio 4 Zn to 1 Cr. The precipitate was washed, dried at 80° in air and then in a current of hydrogen at 300° .

5. Normal zinc chromate was made according to Gröger.¹ The saturated solution of chromic acid was shaken for several days with the proper amount of zinc oxide. The solid was ground up several times during the shaking. The chromate was then filtered free of the supernatant liquid and treated as above.

6. Zinc chromite was precipitated by mixing solutions of zinc nitrate and of chromium chloride dissolved in an excess of sodium hydroxide. The precipitate was washed and dried as above.

7. Copper hydroxide equal to 5% of the weight of the zinc oxide was added to the preparation (1) before addition of the chromic acid. Zn:Cr = 4:1.

8. Dry zinc carbonate (prep. 3) was mixed with moist, precipitated chromium hydroxide in the atomic proportions Zn:Cr = 4:1. The product was washed, dried and heated to 350° in a vacuum as above.

9. A solution of sodium carbonate was added to a solution of zinc and chromium nitrates in the ratio 4 Zn:1Cr. The precipitate was washed and dried as before, and then heated to 350° in a current of methanol for 45 minutes.

10. Cadmium chromate was prepared as for zinc chromate in prep. (2).

11. Cadmium chromate was prepared as for zinc chromate in prep. (1), the proportions being 1Cd:1Cr. This preparation was reduced with hydrogen at 200° .

12. Cadmium carbonate, prepared by adding a solution of sodium carbonate to a hot solution of cadmium nitrate and washing, was heated in a vacuum for 15 minutes at 400° . The surface of the product was brown, due to formation of the oxide, while the interior was light yellow.

13. A hot solution of cadmium and manganese chlorides, in the proportions of 4Cd:1Mn, was precipitated with a solution of potassium hydroxide. The precipitate was washed and dried in air at 100° and then in hydrogen at 300° .

14. A solution of uranyl nitrate was boiled with cadmium hydroxide. The proportions were 1Cd:1U. The product was dried and reduced as usual.

15. 39 g. moist cadmium hydroxide was mixed with 48 g. moist zinc hydroxide. The product was dried in air at 80° and then in hydrogen at 350° .

16. Zinc uranate was prepared by boiling zinc carbonate with a solution of uranyl nitrate until no more CO_2 was evolved. The proportions were 1Zn:1U. The product was dried and reduced as usual.

¹ Z. anorg. Chem., 70, 135 (1911).

17. An excess of a solution of zinc nitrate was added to a solution of ammonium vanadate. Ammonia was added to the mixture slowly with stirring until most of the vanadium was precipitated. The precipitate was washed, dried and reduced with hydrogen at 300° , and later with methanol.
18. Vanadic acid was made by boiling a concentrated solution of ammonium vanadate with nitric acid. The precipitate was washed and boiled with zinc hydroxide. The product was reduced with hydrogen and methyl alcohol at 300° - 350° . The proportions were (a) $4\text{Zn}:\text{V}$ and (b) $10\text{Zn}:\text{V}$.
19. Zinc molybdate was made by mixing solutions of zinc nitrate and sodium molybdate. The product was washed, dried and reduced with hydrogen at 300° .
20. A hot solution of zinc and aluminum sulfates was precipitated by adding ammonia. The proportions were $4\text{Zn}:\text{Al}$. The precipitate was washed free of sulfate, dried at 100° and then at 300° in a current of hydrogen.
21. A hot solution of zinc nitrate and ferric chloride was precipitated with ammonia. The proportions were $4\text{Zn}:\text{Fe}$. The precipitate was washed, dried, and reduced at 300° .
22. A hot solution of zinc nitrate and manganous chloride was precipitated first with ammonia and then with potassium hydroxide. The proportions were $4\text{Zn}:\text{Mn}$. The precipitate was washed, dried, and reduced with hydrogen at 300° .
23. 60 g. of moist ammonium uranate and 9 g. moist copper hydroxide were mixed and dried at 85° . The mass was then heated in hydrogen at 400° - 500° .
24. 14 g. of the moistened preparation (23) were mixed with 3.6 g. moist zinc oxide. The product was reduced in hydrogen at 400° for 5 hrs.
25. A high grade commercial zinc oxide (made by burning pure zinc) was moistened with water, pressed and dried.
26. A solution of zinc nitrate was precipitated with ammonia. The precipitate was washed, pressed and dried.
27. Acid-washed pumice was saturated with a solution of zinc nitrate. The mass was heated for several hours at 300° in a current of hydrogen.
28. Ammonia was added to a hot solution of zinc and beryllium nitrates in the proportions $4\text{Zn}:\text{Be}$. The precipitate was washed and dried as usual.
29. Ammonia was added to a hot solution of beryllium nitrate. The precipitate was washed and dried as usual.
30. The beryllium oxide from prep. (29) was mixed with chromic acid in the proportions $4\text{Be}:\text{Cr}$. The product was dried in air at 80° and then in hydrogen at 300° .
31. Magnesium oxide was mixed with chromic acid in the proportions $1\text{Mg}:\text{Cr}$. The product was dried in air at 80° and then in hydrogen at 300° .
32. A mixture of magnesium and ferric hydroxides was prepared in the proportions $4\text{Mg}:\text{Fe}$ as for prep. (21).
33. Magnesium uranate was made from magnesium oxide as for zinc uranate in prep. (16).

34. A solution of sodium chromate was added to a warm solution of strontium nitrate. The precipitate was washed by decantation several times. It was dried, pressed and reduced with hydrogen at 300° .

35. A hot solution of chromium nitrate was precipitated by ammonia. The precipitate was washed, dried in air at 80° and then in hydrogen at 300° .

36. The vanadic acid as in prep. (18) was dried, pressed and reduced, first with hydrogen at 300° and then with methanol at 300° and at 350° .

Experimental Results

The experimental data are presented in Figs. 1 and 2 and in Table I. Fig. 1 shows the type of curves obtained at different rates of flow of methanol

FIG. 1
Efficiency of Catalysts

over the catalyst and at different temperatures. Table I contains the data which are not included in Figs. 1 and 2. In Table I and Fig. 2 the rate of flow of methanol is in all cases 0.08 g. per minute. This rate of flow over the 17.1 cc. of catalyst at 300° represents a space velocity of 412 in the usual units of volumes of gas per hour per unit volume of catalyst. In all experiments referred to hereinafter, except as noted otherwise, the rate of flow was 0.08 g./min., the temperature of the catalyst during the test was 300° , and the volume of catalyst was 17.1 cc. All of the catalysts for which the data are presented in Fig. 1 were merely broken into uniform pieces and not run through the press. This is also the case for the lower curve of Fig. 2. The numbers in parentheses on the curves of Fig. 1 indicate the preparation numbers for the respective catalysts.

The data in Fig. 1 indicate that the normal zinc chromate, prepared as in method (5) by long continued mixing of ZnO with an excess of chromic acid, is less active than the catalyst containing the same proportions of zinc and chromium but made as in method (1) by merely adding to ZnO the requisite amount of chromic acid in a small amount of water. This is probably due to the fact that in the former case, more opportunity is given for the chromate crystals to grow. The activity of the catalyst made as in method (1) and containing 2Zn:1Cr is however about the same as the activity of the precipitated catalyst containing the same proportions of zinc and chromium. Cadmium chromate, although it reduces in use, still retains a considerable ac-

FIG. 2
Effect of composition on catalytic activity

tivity—probably somewhat greater than that of the corresponding zinc chromate. The curves also show that the activity of the zinc-chromium catalysts increases as the ratio of zinc to chromium increases from 1 to 4.

Fig. 2 shows that there is an optimum ratio of zinc to chromium at about the atomic proportions 4Zn to 1Cr. All of the catalysts used here were made by a uniform procedure (No. 1). The two curves represent the data on two series of preparations having somewhat different surface areas as explained previously. They both show a maximum of activity in approximately the same place. The points for the upper curve also show the order of reproducibility obtainable, each point representing a separate preparation of the catalyst.

In Table I the best catalysts have, in general, been placed first. ZnO from the carbonate and the 4Zn:1 Cr catalyst (method 1) are of about equal activity. The zinc-chromium catalyst made by precipitating the hydroxides with ammonia appears to be somewhat less active than that made from ZnO

*The catalyst in these experiments was broken into pieces instead of run through the press, as described above. The relative surface by the two methods can be obtained from Fig. 2.

and chromic acid. The former also gives somewhat more CO_2 in the gases of decomposition. ZnO from the carbonate is not further activated by mixture with chromium hydroxide. Reference from Table I to Fig. 2 shows that the Zn-U catalyst is more active than the Zn-Cr catalyst of the same atomic proportions. It gives about the same amount of CO_2 in the gas as does the Zn-Cr catalyst made from the hydroxides. Zinc-vanadium catalysts give very large decompositions but much of the carbon appears as CO_2 . Beryllium chromate, placed near the bottom of the Table, is also a fairly good catalyst.

Cadmium chromate, since it gives a considerable decomposition even at 203° , seems more active than zinc chromate—at least before it has suffered appreciable reduction. Magnesium chromate, however, is less active than zinc chromate. It seems likely, then, that the least stable chromate of these is the most active catalyst.

The zinc chromite which was precipitated from strongly alkaline solution had about the same activity as that of ordinary precipitated zinc chromate.

Although it is reported by Audibert¹ that the so-called sub-oxides of chromium and uranium are good catalysts, it is evident from Table I that these oxides as they were prepared in the present work are not good catalysts. It is rather the mixtures of these oxides with zinc oxide which are good catalysts. Uranium oxide alone seems to produce chiefly a decomposition to formaldehyde and hydrogen, as the gas analysis and tests on the condensate showed. Chromium oxide gave a large decomposition but much of the carbon appeared as CO_2 . Furthermore, about 50% of the condensate in the latter case evaporated while the condenser was warming from the temperature of carbon dioxide snow to room temperature. The nature of this volatile product was not determined, but it is probably methyl ether. It is evident, however, that the catalytic effect of these oxides alone is specific and quite different from that of their mixtures with zinc oxide. Very little of the specific catalytic effect of the chromium or uranium oxides appears when these oxides are mixed with ZnO . Some light was thrown on this point through preliminary results of X-ray powder photographs of these substances which were taken with the assistance of Mr. F. E. Frey. X-ray photographs of ZnO and of Cr_2O_3 showed, of course, the characteristic lines of these substances. A simple mixture of these two dry oxides in the atomic proportions of 2Zn to 1Cr showed the lines of both oxides. The precipitated zinc chromate showed its characteristic lines. After the latter had been reduced at 300° with hydrogen and used as a catalyst it assumed a grayish appearance and presumably was a mixture of ZnO and Cr_2O_3 . Its powder photograph, however, showed none of the lines of Cr_2O_3 and only the apparently undisplaced lines of ZnO together with three faint extraneous lines and a slight general blackening of the film. The atomic proportions of zinc to chromium in this chromate should be 2:1. A catalyst with the same proportions of zinc and chromium made by method (1) was also photographed after it had been reduced. It showed the same thing as did the reduced precipitated chromate. It is likely, then that the

¹ *Chimie et Industrie*, 13, 186 (1925).

Cr_2O_3 in these catalysts does not exist in the ordinary form. It is perhaps either amorphous or has combined with ZnO . This would, then, explain why in the mixed catalyst the specific catalytic effect of the Cr_2O_3 does not appear. It is perhaps worthy of remarking in this connection that ZnO and Cr_2O_3 both have hexagonal crystal structure and there is the possibility of solid solution or mixed crystal formation. BeO , also hexagonal, makes a fairly good catalyst in the presence of Cr_2O_3 .

One experiment was made on a zinc chromate catalyst (method 5) in which nitrogen saturated with methanol at room temperature (v.p. 100 mm.) was passed over the catalyst. The same per cent decomposition was effected as with methanol at atmospheric pressure. The rate of the decomposition reaction thus is first order with respect to the pressure of methanol.

A number of experiments were made on ZnO alone. A product made by precipitation of hot zinc nitrate solution with ammonia (method 26) gave, at 300° and the usual rate of flow of methanol, about 3-4% decomposition. A commercial ZnO , made by burning zinc vapor, gave 13%. It was found, however, that subsequent treatment greatly altered the activity of the ZnO . For example, this same catalyst of commercial ZnO , after use in an experiment at 300° , was cooled to room temperature in an atmosphere of dry CO_2 , then reheated to 300° in an atmosphere of methanol. It now gave 27.5% decomposition. The process was repeated, except that the catalyst was inadvertently heated to 400° just before testing. It now gave 35.4% of decomposition. This catalyst after standing at room temperature in a stoppered bottle for several weeks gave on retesting 16% decomposition. Another sample of the same commercial ZnO at first gave 9.7% and then after heating to 400° for $\frac{1}{2}$ hour and again testing at 300° gave 22% decomposition. After this test the catalyst was heated to 350° in an atmosphere of methanol and again tested at 300° . It still gave 22%. This process was repeated with a fresh sample of ZnO . It first gave 13.0% and after heating to 400° for 15 minutes gave 25.1%. After heating to 400° for 1 hour in an atmosphere of methanol this catalyst had decreased in activity to 6%. The catalyst was then allowed to cool in a stream of CO_2 and was kept overnight in an atmosphere of CO_2 . The next morning the catalyst was heated to 350° for 45 min. in a stream of methanol. It then gave 15.5% decomposition at 300° . The ZnO catalyst is thus affected both by heat treatment and by the presence of dry CO_2 . It was found that the ZnO made from precipitated hydroxide could also be affected in the same way.

An experiment was made with a zinc chromate catalyst to which had been added about 5% of copper hydroxide (prep. 7). The reduction of the chromate was carried out at 250° instead of 300° and a test was made at 300° . A somewhat larger decomposition was obtained than with this catalyst without copper but this result was found to be due to incomplete reduction. A subsequent test gave the usual decomposition.

A zinc-chromium catalyst (at proportions 4:1) which had been standing in a stoppered bottle for several weeks was again tested. It gave 67.3% instead of the usual 59%. After passing a stream of CO_2 over this catalyst the temperature was let fall from 300° to room temperature and the catalyst

was left overnight in an atmosphere of CO_2 . It was then tested and gave 83% decomposition. The passage of moist CO_2 over this catalyst brought the decomposition down to 48%.

The materials used in the preparation of the catalysts were not specially purified: Commercial c.p. chemicals were used. Tests, however, showed the absence of iron and of manganese. The small amounts of CO_2 and CH_4 formed in the experiments can hardly be due to the presence of impurities in the materials used and must be considered as by-products whose formation is catalyzed by the same materials which catalyze the principal reaction. In the case of the Zn-Cr catalysts the amounts of CO_2 and CH_4 did not vary much with changing proportions of zinc and chromium.

The catalysts containing uranium and vanadium were hard to reduce and were pyrophoric. The chromium catalysts, however, did not seem to oxidize when brought into the air after use.

Some of the earlier experiments recorded here were made with the assistance of Mr. Cyrus G. Dunkle to whom the authors wish to express their thanks.

The authors wish to take this opportunity to express their appreciation to Mr. A. C. Fieldner whose interest and encouragement as Chief Chemist of the Bureau of Mines made this work possible.

Summary

1. The decomposition of methanol vapor on various catalytic materials has been measured. Zinc oxide made by igniting zinc carbonate; mixtures of zinc oxide and chromic acid in the atomic proportions $4\text{Zn}:\text{Cr}$; mixtures of zinc oxide and uranium oxide and, perhaps, also mixtures of zinc oxide and vanadium oxide and of cadmium oxide and chromic acid would be considered very good catalysts for the decomposition of methanol into carbon monoxide and hydrogen. These substances should also be good catalysts for the formation of methanol from water gas.

2. The activity of pure ZnO and also of zinc oxide-chromium oxide catalysts is to a considerable degree dependent on the heat and other treatment to which they are subjected.

3. The specific catalytic effect of pure chromium oxide is absent in the zinc oxide-chromium oxide catalysts. X-ray powder photographs indicated the reason for this.

4. Practically all catalysts studied yielded at least a small amount of CO_2 in the gases of decomposition. The CO_2 probably is not due to foreign material in the catalyst but is to be regarded as a by-product of the principal reaction.

TEMPERATURE OF COAGULATION OF PURE COPPER COLLOIDAL SOLUTION

BY B. M. REID AND E. F. BURTON

I. Introduction

The original intention of the experiments detailed herewith was to determine the relation between temperature and coagulation in Bredig copper sols to which electrolytes had been added. As the work developed it was shewn that there are indications that for every given sample of such col-

FIG. 1

loidal solution even when practically free from electrolytic impurities there exists a definite temperature at which coagulation takes place automatically.

The references in the literature to temperature effects have chiefly to do with the change in the velocity of electrolytic coagulation with temperature. Regarding the influence of merely heating pure colloidal solutions, Freundlich¹ says: "Sols behave very differently upon simple warming, even

¹ Freundlich: "Colloid and Capillary Chemistry", p. 467.

without the addition of a coagulant. Many such, as numerous sulphides, (e.g. arsenious and gold), hydroxides (e.g. ferric), metals (e.g. gold sols in alkaline solution) bear long continued boiling without flocculating; others, as in particular many metallic sols, (e.g. platinum) coagulate quickly on warming." Most of these references are to work before 1900, when the influence of small traces of impurity dissolved from the glass vessels may have been lost sight of; at any rate, conditions were complicated by allowing ebullition to take place thus causing constant violent stirring of the sol.

2. Experimental

a. *Method:* The procedure in the following experiments was very simple; a sample of colloid was sealed in a tube which was heated to any desired constant temperature for half an hour. No ebullition took place at any time. Fig. 1 shows the arrangement of the apparatus. The tube containing the colloid was enclosed in a sealed Pyrex tube which was heated in a glycerine bath.

The arrangement for heating the glycerine is shown in the diagram. The electric furnace consisted of a cylindrical copper vessel 19 cms. in height and 11 cms. in diameter, surrounded by a coil of wire which was covered with asbestos to within 1 cm. of the top. A copper lid fitted tightly over the top of the furnace which was filled with glycerine having a boiling point of 290°C . The end of the condenser for the glycerine and a thermometer of range 0°C to 200°C were inserted in a cork fitting into an opening in the centre of the lid. The furnace was connected to the 110 D.C. in series with a Zenith variable resistance coil and an ammeter.

The first determinations were attempted using ordinary glass tubes and afterwards Pyrex tubes as containers of the colloid sample. It was found, however, that as the temperature was raised impurities dissolved from the glass, and produced coagulation. This was detected by the very great increase in the conductivity of the sol after heating. With the substitution of a copper tube as the inner container, this difficulty was eliminated; the resistance was always measured both before and after every determination, as a check on the introduction of impurities. There was almost invariably some decrease in resistance, but, where this decrease was great enough to be comparable to the addition of an active electrolyte, the result was discarded.

The copper tube used was cylindrical in shape, 10 cms. long and 1.5 cms. in diameter; the most convenient amount of colloid to use in a tube of this size was found to be 12 cc. After this amount of solution was placed in the tube the resistance was measured, using two platinum electrodes made so that they could be inserted directly into the copper tube. When not in use, these electrodes were kept in conductivity water to insure cleanliness. The tube containing colloid was then dropped onto glass wool in the bottom of a thick-walled Pyrex tube, of diameter about 2 cms. Water was introduced into the glass tube up to about 2 cms. from the top of the copper tube by means of a long narrow funnel and the tube was then sealed off at a length of about 17 cms.

Half an hour to one hour was taken to raise the temperature of the glycerine to the desired point using a current of about 5 amps., which was then reduced to a value that would maintain the given temperature for one half hour. At the end of this time the tube was removed and allowed to stand at room temperature for four hours. Then the glass tube was opened, the copper tube removed, and the resistance again measured, thus checking the introduction

Jan. 4, 1927, colloid in stock bottle coagulated.

of coagulating factors other than the temperature. The colloid was then poured into a test-tube and it was observed whether it had coagulated or not.

b. *Results.* (i) The first solution of copper colloid with which experiments were carried out was made by sparking wires in 2400 ccs. of conductivity water. *After the colloid was made* 24 drops of 0.1N potassium chloride were added. The results obtained are given in Table I, which shows the temperature at which coagulation takes place as the colloid sample ages.

After an absence of four months the colloid was found coagulated on September 15.

(ii) The second solution tested was copper colloid made by sparking wires in 2400 ccs. conductivity water *to which had been added just before sparking* 20 drops of 0.1 N potassium hydroxide solution. This colloid was made on October 7, 1926, and Table II gives the results.

The date of each determination is given and the results are divided into groups on this basis. In each group temperatures have been obtained showing the limits of coagulation and no coagulation; the mean of these temperatures might be called the temperature of coagulation of the colloid at that particular time in its history.

The two samples for which the above results were obtained were evidently undergoing slow coagulation, in which process the size of the particles increases until it exceeds the limiting size for which the Brownian movement masks the gravitational pull and the particles settle out of the suspension. It is apparent, then, that this temperature of coagulation decreases as the particles increase in size.

(iii) For a suspension of copper in conductivity water such that an equilibrium state exists when the coagulation is extremely slow, the temperature of coagulation would be a unique property of the solution and a function of the size of the particles. It was thought that it might be possible to determine the form of this function and for this purpose a third sample of copper colloid was prepared by the same method of sparking between wires. This time the sparking was done in conductivity water *to which no electrolyte was added either before or after the sol was made.* Then three samples of 200 ccs. each were transferred to carefully cleaned bottles, which had been allowed to soak in successive washes of conductivity water for two weeks. Six, fifteen, and twenty-four drops of 0.01 N potassium chloride solution were added to these three samples respectively, and they were allowed to stand undisturbed for a week or ten days before any determinations were made. Table III gives for each solution the limits of temperature between which lies the coagulation temperature of the solution.

Whether the solutions in which the electrolyte was added were undergoing slow coagulation or had attained a condition of equilibrium is doubtful. It seems, however, certain that in the case of the stock solution a condition of equilibrium exists. At any rate there appears to be a definite relation between the coagulation temperature and the concentration of electrolyte, and a curve, Fig. 2, has been drawn for the values obtained. For the three solutions containing electrolyte the relation is very nearly linear. Under the conditions

TABLE III

Concentration of electrolyte - KCl -	Uncoagulated at Temperature	Coagulated at Temperature	Days after addition of electrolyte
0	180°C	185°C	
0.97×10^{-6}	142°C	146°C	33
2.40×10^{-6}	138°C	140°C	20
3.84×10^{-6}	131°C	134°C	19

FIG. 2

of the experiment for these results to be strictly comparable, if the solutions were slowly coagulating, determinations should have been made when the same time had elapsed after the addition of electrolyte for each solution. If this had been done and the determination of the coagulation temperature for the solution with a concentration of KCl 0.97×10^{-6} had been made 20 days after the addition of electrolyte the result would have been slightly higher and the curve for these three points more exactly a straight line. The assumption that the temperature of coagulation would have been higher at that time is justified from the results given previously.

It is consistent with colloidal theory in connection with coagulation to assume that the solutions to which increasing amounts of electrolyte were added will contain particles of correspondingly increasing sizes at least after the same interval of time has elapsed since the electrolyte was added.

Hence the results agree in indicating that the coagulation temperature is a function of the size of the particles.

Attempts were made to observe the difference in size of the particles by means of the ultramicroscope count. These did not yield definite results, but exact measurement of the light scattered by the various samples showed a progressive change as the amount of electrolyte added increased.

3. Theoretical Considerations

We undoubtedly have to do with two separate cases:

(i) The purest and simplest form of sol can be coagulated by increase of temperature alone, and

(ii) During the process of slow coagulation induced by traces of electrolyte, coagulation may be made "rapid" by increase of temperature.

These experimental results confirm a very simple view of what is going on in such a colloidal solution as this copper sol. There is not the slightest doubt that such sols as these Bredig metal sols exist practically unchanged for great lengths of time without the aid of protective colloids; of course, one may say that there is always slow coagulation, which is a relative term, but the rate of coagulation for many of these sols is at the best very very slow. This stability is due to (1) the slow rate of fall of small particles under gravity, (2) the disturbance due to the Brownian movement, and (3) the prevention of any noticeable coalescence of particles due to their mutual repulsion.

In presenting the theories of rapid and slow coagulation, Smoluchowski¹ arrived at formulae which indicate the way in which the number of particles of various sizes in a suspension will vary with time due to the aggregation as a result of collisions brought about by the Brownian movement. The assumption is made, following Zsigmondy, that around each particle is a sphere of attraction of definite radius, and, if two particles approach during molecular motion so closely that the centre of one enters the sphere of attraction of the other, they would remain adherent and not separate again. But this assumption is not necessary to the establishment of the Smoluchowski formulae; in fact, the experimental confirmations of these formulae show that the two particles reach this critical position when they touch or nearly so. If they touch, surface tension forces would account for their sticking together.

The simplest explanation seems to be that, as a result of the molecular motion in the liquid medium, the particles are driven hither and thither, and collisions certainly would be very frequent if there were no forces tending to keep the particles separated. Frequent collisions are prevented by the natural repulsion of the particles due to their like electrical charges. The mutual repulsion is not exercised until two particles are quite close together but the force can be very great when the particles approach one another very closely. The reason lies in the distribution of the Helmholtz layer; it is quite generally accepted now that this outer layer is diffuse, as suggested by Gouy,² and that it may be several molecular diameters in thickness. When two neighboring particles approach one another so that these outer Gouy layers overlap, the

¹ See Svedberg: "Colloid Chemistry", p. 215.

² J. Phys., (4) 9, 457 (1910).

particles will possess an effective charge relatively to one another and consequently repel one another. But it is always conceivable that on occasion the Brownian movement may be so directed and of such intensity that the two particles might possibly touch in spite of this repulsion.

The frequency of such occurrences will be increased (i) by increasing the intensity of the Brownian movement, i.e. increasing the temperature or (ii) by decreasing the thickness of the Gouy layer (the outer Helmholtz layer) which may be accomplished by adding electrolytes to the medium or (iii) by decreasing the size of the charge on the colloidal particle, which is supposed to be caused by adsorbed electrolytic ions.

Such considerations offer a simple explanation of the experimental results recorded above. No colloidal solution will remain uncoagulated under a continuously increasing temperature. The higher the temperature the greater the molecular motion; when the motion becomes so violent that the particles are pushed into collision in spite of the electrical charge, coagulation automatically intervenes. If to the pure sol, slight traces of an electrolyte are added, the charge is reduced, the Gouy layer is depressed, collisions are not opposed by such great forces, and therefore the automatic coagulation takes place at lower temperature.

The curve given in Fig. 2 suggests a logarithmic relation between the temperature of coagulation and the concentration of the electrolyte. Attempts to get a quantitative relation between these two variables suggest the work of Arrhenius¹ and others on the relation between temperature and chemical reaction. The various suggested formulae are particular cases of a general one:

$$\frac{d \log K}{dT} = \frac{A + B T + C T^2 + \dots \text{etc.}}{T^2}$$

where T is the absolute temperature, K is the rate of a chemical reaction, and A, B, C, \dots are constants. Arrhenius' form which is the equivalent of putting all the constants except A equal to zero may be written thus:

$$K_{T_1} = K_{T_0} e^{\frac{A}{T_0 T_1} (T_1 - T_0)}$$

where the K_{T_1} and K_{T_0} are rates at temperatures T_1 and T_0 and A is a constant. Arrhenius found good agreement with this formula in testing the inversion of sugar by acids and Miyazawa's² experiments on the slow flocculation of aluminum oxide sols, agreed with the formula also. However, Arrhenius points out that in the case of ordinary chemical reaction, the increase per degree rise in temperature is very large—much larger in fact than such phenomena as that dealt with by Miyazawa. Arrhenius also shows that the increase in ordinary purely chemical actions cannot be accounted for by such physical changes as the increase with temperature in the number of collisions per second between molecules or the decrease in the viscosity.

¹ Z. physik. Chem., 4, 226(1889); see Mellor: "Chemical Statics and Dynamics", 386 et seq.

² Freundlich, loc. cit., p. 465.

There are at least three distinct ways in which the increase in temperature may assist coagulation of sols such as recorded above:

(i) Increase in molecular motion, rate of diffusion, Brownian movement, viscosity, and all phenomena due primarily to molecular motion; these are all accounted for in the Smoluchowski formula for slow coagulation which shows that as far as the temperature is concerned the rate of coagulation varies as T/n where T is the absolute temperature and n is the coefficient of viscosity of the medium at the temperature T .

(ii) Since we are dealing with a phenomenon which involves electrical forces between charged bodies in a medium, the force will vary inversely as the dielectric constant of the medium—a quantity which certainly changes with temperature. The role of the dielectric constant in the action of electrolytes is most important as indicated by the work of Debye and Hückel and others. However, the experimental work on the variation of this coefficient with temperature for water does not indicate any remarkable change. The equation which has been found to hold is:¹

$$D_{T_1} = D_{T_0} [1 - \alpha(T_1 - T_0) + \beta(T_1 - T_0)^2]$$

where $\alpha = 0.0045$ and $\beta = 0.000017$. The variation given by this formula between 20°C and 180°C amounts to only 30% at the most. This 30% is a decrease in the value of the dielectric constant which means an increase in the electrical field between charged bodies in the medium—a circumstance which would tend to make the sols more stable.

(iii) The most likely change with temperature which will be effective in causing this coagulation is the change in the ionization of the water itself. Kraus² records the change in the ionization constant for water as the temperature changes in Table IV.

TABLE IV

Ionization constant for water

Temperature	0°	18°	25°	100°	150°	218°	306°
$K_w \times 10^{14}$	0.089	0.46	0.82	48	223	461	168

These results are plotted in the curve II of Fig. 2 which suggests a very striking relation between the change in the ionization constant and the coagulating effect of a change of temperature. However, the suggestion cannot be pressed too far, as all of these effects are undoubtedly bound up together—viz., molecular motion, viscosity, diffusion, dielectric constant, and so on.

The conclusion, however, seems to be inevitable that a sufficient rise in temperature can of itself cause the coagulation of any colloidal solution of the dispersoid type and any process of slow coagulation can be changed to rapid coagulation by a definite rise in the temperature.

AMMONOUS NITRIDES

(I) Ammonous Cobaltous Nitride, Ammonous Aluminum Nitride and Stannous Imide

BY F. W. BERGSTROM

Introduction: Ammonous Cobaltous Nitride

Some years ago the author prepared a bulky blue precipitate¹ approximating cobaltous amide, $\text{Co}(\text{NH}_2)_2$, in composition by pouring a liquid ammonia solution of potassium amide—a base of the ammonia system²—into a solution of cobaltous thiocyanate, the reaction proceeding in accordance with the equation, $(1) \text{Co}(\text{SCN})_2 + 2\text{KNH}_2 = 2\text{KSCN} + \text{Co}(\text{NH}_2)_2$. Rather strangely, this precipitate loses ammonia slowly and irreversibly under liquid ammonia at room temperatures, and therefore at about eight atmospheres pressure, to form black cobaltous nitride in the manner expressed by the equation, $(2) 3\text{Co}(\text{NH}_2)_2 = \text{Co}_3\text{N}_2 + 4\text{NH}_3$. Since this reaction takes place much more slowly at -40° than at room temperatures, it seemed possible that cobaltous nitride might take up ammonia at still lower temperatures to form cobaltous amide in accordance with equation (2) read from right to left. However, cobaltous nitride does not appear to absorb ammonia at the temperature of an ether-carbon dioxide snow mixture.

There is a rather interesting parallelism between the properties of cobaltous amide and cupric hydroxide, for the blue cupric hydroxide slowly and irreversibly loses water at ordinary temperatures to form black products approaching cupric oxide in composition,³ just as the blue cobaltous amide loses ammonia and is converted into black cobaltous nitride. It has often been suggested³ that cupric hydroxide is a hydrous or solvovous cupric oxide, $\text{CuO} + x\text{H}_2\text{O}$, rather than a definite compound, $\text{Cu}(\text{OH})_2$. Reasoning from the analogy known to exist between the amides, imides and nitrides of the ammonia system and the hydroxides and oxides of the water system⁴ cobaltous amide should perhaps be formulated as a solvovous or ammonous cobaltous nitride, $\text{Co}_3\text{N}_2 + x\text{NH}_3$.

The present investigation was undertaken for the purpose of preparing other metallic amides and imides whose properties might allow them to be formulated as ammonous nitrides.

⁴ Franklin: J. Am. Chem. Soc., **46**, 2139 (1924); Am. Chem. J., **47**, 289 (1912).

Ammonous Aluminum Nitride

The basic amides are most readily obtained by pouring a solution of potassium amide into a solution of a metallic salt in liquid ammonia. Thus, cobaltous "amide" is easily prepared by the action of potassium amide upon a solution of cobaltous thiocyanate in accordance with equation (1) just as cobaltous "hydroxide" is obtained by the action of an aqueous solution of potassium hydroxide upon a water solution of the same salt of cobalt. Attempts of Franklin¹ to prepare aluminum amide by the action of potassium amide upon a liquid ammonia solution of aluminum iodide failed because an insoluble ammonobasic iodide of aluminum was precipitated. The author found that potassium amide similarly precipitated an ammonobasic aluminum thiocyanate from a solution of aluminum thiocyanate.²

Since acids precipitate aluminum hydroxide³ from aqueous solutions of alkali metal aluminates, it is to be expected that aluminum amide would likewise be precipitated by the action of an acid upon a solution of potassium or sodium ammono aluminate, in accordance with the equation (3):

The sodium ammono aluminate required in this reaction was first made by the action of a liquid ammonia solution of metallic sodium upon amalgamated aluminum in a two-legged reaction tube, following the earlier directions of the author.⁵ The solution of sodium ammono aluminate formed in this manner was then decanted into the other leg of the reaction tube, leaving the residue of unused aluminum behind. With this solution cooled in a bath of liquid ammonia, the leg containing the residue was opened and cleaned out.⁶ Into this leg was then introduced a little less than the quantity of ammonium bromide calculated for the reaction of equation (3), after which the leg was sealed shut and the apparatus allowed to warm to room temperature. With the leg containing the ammonium bromide immersed in an ice bath and the other leg in warm water, ammonia was distilled over to form a dilute solution of ammonium bromide. This latter was poured slowly into the solution of sodium ammono aluminate in the other leg of the reaction tube until a sufficiently large precipitate of aluminum "amide" had been formed. The precipitate was washed thoroughly and then allowed to stand under pure liquid ammonia for the period of time indicated in the following table. (The figures given include the time consumed in washing the precipitate). Since aluminum "amide" reacts vigorously with water the specimens were

^a Prepared from potassium ammono aluminate.

^b Found to contain 3.8 percent sodium.

Discussion—It is evident from an examination of the above table that the substances precipitated by pouring a liquid ammonia solution of ammonium bromide into a solution of sodium or potassium ammono aluminate are not constant in composition, even though some of the specimens (Nos. 1, 2, 3, 4) were prepared in almost the same manner. It was thought that the lack of agreement in the analyses might be due to the differences in purity of the preparations, but this seems improbable in view of the fact that the total amount of halogen and alkali metal present as impurities varies from a few tenths of a percent in preparations No. 1 and 2 to a little under four percent in preparation¹. One should not expect impurities in the amounts found to have such a profound influence upon the composition of the specimens. For other metallic amides which have been prepared are much more constant in composition, in spite of contamination with several percent impurity.²

Since aluminum forms very basic salts in liquid ammonia, it was thought possible that the preparations might be mixtures of highly basic aluminum

¹ These amounts were estimated roughly by comparison of the sum of the percentages of aluminum and nitrogen found with the sum of the percentages of these two elements calculated for pure compounds of Al, N and H having the same atomic proportion of nitrogen to aluminum. Preparation 7 was found on analysis to contain 3.8 percent sodium.

² For instance, manganese amide and some specimens of magnesium amide. Bergstrom: J. Am. Chem. Soc., 46, 1557 (1924); 48, 2851 (1926).

bromides or highly acidic sodium ammono aluminates¹ whose differences in composition might account for the divergent analyses. Thus, the composition of preparation 2 agrees approximately with the formula $\text{Al}(\text{NH})\text{NH}_2$, or for that matter with the general formula $\text{Al}(\text{NH})\text{NH}_2 \cdot x\text{NaNH}_2$, where x is sufficiently large (about 15). No. 7, the least pure specimen, has the approximate composition $4\text{Al}_2(\text{NH})_3 + 4\text{AlN} + \text{NaNH}_2$, since the impurity is chiefly sodium. Thus, in preparation 2, sodium amide is in combination with 15 molecules of $\text{Al}(\text{NH})\text{NH}_2$ and in preparation 7 with 4 molecules each of $\text{Al}_2(\text{NH})_3$ and AlN . If these acidic aluminates are definite compounds, one certainly should not expect such a variation in the composition of the aluminum-containing portion of the molecule. Moreover, the existence of amorphous compounds of such molecular complexity is very improbable. It is more reasonable to consider that the preparations contain different amounts of adsorbed impurity.

Now the specimens, dried in a vacuum at room temperatures change in composition from No. 1, an aluminum amide which has lost almost enough ammonia to form aluminum imide-amide, $\text{Al}(\text{NH})\text{NH}_2$, to Nos. 6 and 7, which appear to be partially deammonated aluminum imides, $\text{Al}_2(\text{NH})_3$. These differences in composition do not completely disappear even when the preparations are heated in a vacuum above 200° . It would seem in view of the facts enumerated above that the preparations cannot be regarded as definite compounds. It is suggested that they be considered solvates or ammonous aluminum nitrides in the sense that ferric and cupric hydroxides are considered hydrous oxides, $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ and $\text{CuO} \cdot x\text{H}_2\text{O}$.

There are indeed many points of similarity between the hydrous oxides and the substances we regard as ammonous cobaltous nitride and ammonous aluminum nitride. The water content of the hydrous oxides as well as the ammonia content of these ammonous nitrides depends upon the previous history of the specimens. Some hydrous oxides, as for instance hydrous cupric oxide, change into the corresponding oxide under liquid water at ordinary temperatures,² just as cobaltous "amide" changes to cobaltous nitride under liquid ammonia. Ammonous aluminum nitride appears to lose ammonia very slowly in this manner. Thus, preparations 7 and 6, which were washed and kept under liquid ammonia respectively two months and three weeks prior to analysis contain less nitrogen than the other specimens. The change of the blue gelatinous cupric "hydroxide" into cupric oxide may be prevented or greatly retarded by the presence of adsorbed salts or metallic hydroxides.² It is possible that the differences in the composition of the specimens of ammonous aluminum nitride may in part be due

¹ Basic salts may be represented for purposes of convenience as double compounds of the normal salt with the corresponding base. Thus, the insoluble ammonobasic aluminum iodide prepared by Franklin (J. Am. Chem. Soc., 37, 847 (1915)) may be written as $3\text{Al}(\text{NH}_2)_2 \cdot \text{AlI}_3 \cdot 6\text{NH}_3$. Similarly we can represent an ammono "basic" sodium aluminate as the double compound $\text{Al}(\text{NH}_2)_2 \cdot \text{NHNa} \cdot x\text{Al}(\text{NH}_2)_3$, or more simply as $\text{NaNH}_2 \cdot x\text{Al}(\text{NH}_2)_3$. Perhaps it would be more logical to call such substances ammono acidic aluminates, since the amphoteric base aluminum amide has certainly acted as a weak acid in the formation of sodium ammono aluminate.

² Weiser and others: loc. cit.

to varying amounts of adsorbed impurities. It was indeed found that potassium amide reacts with or is adsorbed by solvous aluminum nitride¹. It is impossible to remove this potassium amide by continued washing.

The vapor pressure-composition curve for a hydrous oxide at constant temperature shows no break which would indicate a definite hydrate. Similarly, the vapor pressure-composition curve of the system AlN-NH_3 should show no break corresponding to a definite ammonate of aluminum nitride. In the present work no definite decomposition pressures were observed when specimens of ammonous aluminum nitride were heated in a vacuum, possibly because equilibrium between gas and solid is reached so slowly. A determination of the pressure-composition curve of the system AlN-NH_3 at a series of temperatures is now in progress in this laboratory.²

Many nitrides prepared in liquid ammonia and dried in a vacuum at room temperatures retain small quantities of ammonia which are given off on heating at a higher temperature. Thus, ferrous, cobaltous and nickelous nitrides give off small quantities of ammonia in a vacuum at 100° . It is probable that the liberated ammonia is not ammonia of constitution but ammonia held in the same manner that water is held in the hydrous oxides.

Other Properties of Ammonous Aluminum Nitride.—Ammonous aluminum nitride reacts with solutions of an excess of potassium amide or ammonium bromide to form respectively potassium ammono aluminate and aluminum bromide. Ammonous aluminum nitride in ammonia, like aluminum hydroxide in water, reacts with or adsorbs alizarin with the formation of a colored lake.³ The lake formed by the action of the purplish solution of alizarin in liquid ammonia upon aluminum amide is less stable toward washing than the corresponding lake formed in water. As alizarin contains four atoms of oxygen, it was thought possible that the ammonous aluminum nitride might have been converted to aluminum hydroxide, which would then unite with alizarin to form a lake. It was found that very little if any of the ammonous aluminum nitride was converted to hydroxide by the alizarin, since the lake reacted with water as if it contained $\text{AlN} + x\text{NH}_3$, and since the ratio of Al:N in the precipitate was about what one would expect for a pure ammonous aluminum nitride which had remained in contact with liquid ammonia for the same length of time as the lake.

It was thought possible that an ethyl derivative of aluminum amide, ethyl ammono aluminate, might be prepared by the action of ethyl iodide

¹ An excess of potassium amide dissolves ammonous aluminum nitride to form potassium ammono aluminate. On the other hand, potassium amide reacts with a large excess of ammonous aluminum nitride to form insoluble compounds, or more probably soluble substances which are subsequently adsorbed.

² The failure to obtain a constant pressure corresponding to the equilibrium between a nitride and ammonia gas may not prove that the substance under consideration is an ammonous nitride. Thus it has been found that the deammonation of barium and calcium amides to the corresponding nitrides at elevated temperatures is irreversible. (Kraus: J. Am. Chem. Soc., 45, 2559 (1923). Nevertheless, there can be no doubt of the existence of either calcium or barium amide, for these substances are constant in composition over such a wide range of temperature.

³ This lake is a lighter red than the corresponding water lake.

on a liquid ammonia solution of sodium ammono aluminate, in accordance with the equation, $\text{Al}(\text{NH}_2)_2\text{NHNa} + \text{C}_2\text{H}_5\text{I} = \text{NaI} + \text{Al}(\text{NH}_2)_2\text{NHC}_2\text{H}_5$. The white flocculent precipitate obtained in this reaction was found to be impure ammonous aluminum nitride, signifying that the expected ester was formed and then underwent ammonolysis in accordance with the equation, $\text{Al}(\text{NH}_2)_2\text{NHC}_2\text{H}_5 + \text{NH}_3 \rightarrow \text{C}_2\text{H}_5\text{NH}_2 + \text{Al}(\text{NH}_2)_3 \rightarrow \text{C}_2\text{H}_5\text{NH}_2 + \text{AlN} + \text{XNH}_3$.

Stannous Imide, SnNH , and Stannous Nitride, Sn_3N_2

In view of the fact that ammonous aluminum nitrides are prepared by the action of ammonium bromide upon a solution of sodium or potassium ammono aluminate in liquid ammonia, it was thought that a stannous amide, imide or an ammonous stannous nitride might be prepared by the action of ammonium bromide upon a solution of potassium ammono stannite in accordance with the equation, (4) $\text{SnNK} + \text{NH}_4\text{Br} = \text{SnNH} + \text{NH}_3 + \text{KBr}$. It was found that this reaction takes place readily.

Preparation 1. Potassium ammono stannite was first prepared by the action of a solution of potassium amide in liquid ammonia upon stannous chloride in slight excess of the amount required by the equation, (5) $\text{SnCl}_2 + 3\text{KNH}_2 = \text{SnNK} \cdot 2\text{NH}_3 + 2\text{KCl}$.¹ One leg of the reaction tube used now contained a solution of potassium ammono stannite together with a precipitate of the sparingly soluble potassium chloride and the unused stannous chloride. The other leg of the reaction tube which contained the small tubes from which the potassium had dissolved together with the iron wire catalyst used in the conversion of the alkali metal solution to potassium amide, was opened, cleaned out and resealed². Into this clean leg was then decanted the solution of potassium ammono stannite. Now with this solution cooled to -40° , the leg containing the residual potassium chloride was opened, cleaned out and resealed after introducing enough ammonium bromide for the reaction of equation (4). Stannous imide was obtained as a brown amorphous precipitate by slowly pouring a diluted solution of ammonium bromide into the solution of potassium ammono stannite. After a thorough washing with liquid ammonia the stannous imide was heated in a vacuum, hydrolyzed with water and then dissolved in dilute hydrochloric acid preparatory to analysis. Tin was determined as oxide after previous precipitation as sulfide. Potassium was recovered as sulfate from the filtrate of the stannous sulfide to which sulfuric acid had been added. Nitrogen was estimated volumetrically as ammonia. Subs. dried in a vacuum at 20° , 0.5167 g; heated in a vacuum at 170° , 0.5140 g. One quarter gave 0.1448 g. SnO_2 and one half gave 0.02630 g. nitrogen.

¹ The very slightly soluble stannous chloride first reacts with potassium amide to form the almost insoluble stannous imide, in accordance with the equation, $\text{SnCl}_2 + 2\text{KNH}_2 = \text{SnNH} + \text{NH}_3 + 2\text{KCl}$. Potassium amide dissolves the amphoteric base stannous imide to form potassium ammonostannite, in the manner represented by the equation, $\text{SnNH} + \text{NH}_3 + \text{KNH}_2 = \text{SnNK} \cdot 2\text{NH}_3$, Bergstrom: J. Phys. Chem., 30, 15 (1926).

² Cf. Franklin: J. Phys. Chem., 15, 511 (1911).

Preparation 2. Subs. dried in a vacuum at 20° , 0.2690 g; heated in a vacuum at 200° , 0.2653 g. One half gave 0.1470 g. SnO_2 while the other half gave 0.0128 g. nitrogen.

Preparation 3. Subs. dried in a vacuum at 20° , 0.2917 g; heated in a vacuum at 170° , 0.2890 g; heated in a vacuum at 220° , 0.2876 g. One half gave 0.1608 g. SnO_2 . One half gave 0.01423 g. nitrogen.

Preparation 4. Subs. dried in a vacuum at 20° , 0.3700 g; heated in a vacuum at 175° , 0.3663 g. One quarter gave 0.1021 g. SnO_2 and one half gave 0.01755 g. nitrogen.

Preparation 5. Subs. dried in a vacuum at 20° , 0.3133 g; heated in a vacuum at 180° , 0.3094. One half gave 0.1711 g. SnO_2 and the second half gave 0.01441 g. nitrogen.

Preparation 6. In this experiment, stannous imide was heated to a temperature of 340° in a vacuum for the purpose of preparing stannous nitride, Sn_3N_2 . The product so obtained was not dissolved by the prolonged action of hot solutions of hydrochloric acid or sodium hydroxide, proving therefore to be much more inert than stannous imide, which reacts with water with a slight evolution of heat and dissolves fairly readily in dilute hydrochloric acid.

For the purpose of analysis, the stannous nitride was removed from the reaction tube in suspension in dilute hydrochloric acid and treated with hydrogen sulfide to precipitate a small amount of dissolved tin. The combined precipitates of stannous nitride and sulfide were fused with a mixture of sodium carbonate and sulfur. Tin sulfide was precipitated by acidifying the water solution of this fusion. Subs. dried in a vacuum at 115° , 0.4066; heated in a vacuum at 340° , 0.3894 g. The entire specimen gave 0.4546 g. SnO_2 .

Summary of Analyses

Heated in a vacuum at 150° - 200°

Heated in a vacuum at 340° , No. 6, Sn 92.0. Calculated for Sn_3N_2 , Sn 92.7.

The preparations are all contaminated with small quantities of potassium and halogen. For this reason, the analyses do not agree as closely with the calculated composition of SnNH as might be desired. In view of the constancy in composition of the preparations it is possible that stannous imide is a definite compound and not an ammonous stannous nitride. The question then naturally arises as to whether the small additional amount of ammonia retained by stannous imide at room temperatures is constitutional ammonia, in the form of stannous amide, or adsorbed ammonia. If the latter, it would be necessary to postulate the existence of an ammonous stannous imide, if we assume that the imide is itself a definite compound.

Other Properties of Stannous Imide. Like many compounds of the ammonia system, stannous imide is hydrolyzed by water to ammonia and the corresponding compound of the water system, hydrous stannous oxide or stannous hydroxide. Like the latter stannous imide is an amphoteric base, for it dissolves in a liquid ammonia solution of the base potassium amide to form potassium ammono stannite, and in a solution of the acid, ammonium thiocyanate, to form a soluble thiocyanate of tin.

Potassium ammono stannite may be nitridized to potassium ammono stannate just as potassium aquo stannite is oxidized to an aquo stannate. Thus, crystals of the sparingly soluble potassium ammono stannate, $\text{Sn}(\text{NK})_2 \cdot 4\text{NH}_3$,¹ are obtained when iodine is added to a liquid ammonia solution of potassium ammono stannite containing an excess of potassium amide², the reaction proceeding in accordance with the equation, $\text{SnNK} + 2\text{I} + 3\text{KNH}_2 = \text{Sn}(\text{NK})_2 + 2\text{KI} + 2\text{NK}_3$. Found, Sn 39.2, N 26.3. Calculated for $\text{Sn}(\text{NK})_2 \cdot 4\text{NH}_3$, Sn 40.5, N 28.7. The specimen is thus an impure potassium ammono stannate.

A solution of metallic potassium in liquid ammonia reduces potassium ammono stannite to a soluble potassium tin alloy, K_4Sn_x , which contains the tin in the anion³. The reduction has therefore proceeded beyond the stage of metallic tin.

In conclusion, the author wishes to thank Dr. E. C. Franklin for his interest in this work.

Summary

(1) In order to explain certain anomalous properties of cobaltous amide it has been suggested that this substance is an ammonous cobaltous nitride, $\text{Co}_3\text{N}_2 + x\text{NH}_3$, an ammonia analogue of the hydrous oxides.

(2) It was not found possible to precipitate an aluminum amide, imide, or nitride of definite composition from a liquid ammonia solution of sodium or potassium ammono aluminate. Since the precipitated substances, under comparable conditions, contain from 40.7 to 55.6 percent aluminum and 38.8 to 52.0 percent nitrogen with very little alkali metal or bromine as impurity, it is suggested that they be regarded as ammonous aluminum nitrides, $\text{AlN} + x\text{NH}_3$.

(3) The small amount of ammonia frequently retained by many nitrides prepared in liquid ammonia is perhaps bound in the same manner as the ammonia in $\text{Co}_3\text{N}_2 + x\text{NH}_3$ or $\text{AlN} + x\text{NH}_3$.

(4) Stannous imide, SnNH , and stannous nitride, Sn_3N_2 , have been prepared. Stannous imide may be a definite compound and not an ammonous stannous nitride.

THE SORPTION OF WATER VAPOUR BY ACTIVATED CHARCOALS

PART. I. APPARATUS—TECHNIQUE—NATURE OF CHARCOALS USED

BY P. G. T. HAND AND D. O. SHIELS

1. Introduction

The work to be described in this, and succeeding papers forms part of an investigation carried out in this laboratory under the direction of Professor A. J. Allmand from the commencement of 1921, and still in progress. Its primary purpose has been the establishment of the experimental facts concerning the sorption of vapours by charcoal with a view, of course, of arriving at an understanding of the essential nature of the phenomenon, and of an explanation of the marked differences shown between the behaviour of the vapours of water and of other substances. In addition, whatever the use adsorbent charcoals may be put to, the omnipresence of water vapour makes a study of its sorption relations, in particular, of direct practical importance.

When this work was commenced, the only previous publications on water vapour of importance known to us were those of Schmidt and Hinteler,¹ Bachmann,² and Lowry and Hulett.³ During the course of the work, there have been published or become available to us papers by Rakovsky,⁴ Gustafson,⁵ Hällstrom,⁶ Berl and Andress,⁷ Isobe,⁸ Gustaver,⁹ Katz¹⁰ and Coolidge.¹¹

Two general experimental methods have been employed. In the one ("dynamic" or "streaming" method), a current of air or of nitrogen charged with a known partial pressure of water vapour, by bubbling through sulphuric acid solutions of definite concentrations at 25°C, was passed through a column of charcoal contained in a silica tube at 25°C \pm 0.05° until constancy of weight had been reached. The charcoal had been previously outgassed at a definite temperature, and subsequently saturated with the pure dry gas at 25°C. The purpose of the experiments in the nitrogen stream was to investigate whether or not the presence of oxygen in charcoal has a specific effect on the sorption process.

In the second ("static" or "vacuum") method of experimentation, water vapour, free from any admixed gas, was admitted to the previously evacuated

charcoal (contained, as before, in a silica or glass tube at 25°C), and the change in weight determined when the pressure, read off on a mercury manometer, had become constant. A series of such experiments, by either method, extending from zero water vapour pressure up to saturation at 25°C enabled the sorption isotherm to be plotted. In almost all cases these isothermals were determined with falling as well as rising water vapour pressure, i.e. *desorption* as well as sorption isotherms were investigated. In a few cases (with the "static" method) experiments were made at temperatures other than 25°C .

FIG. 1a

FIG. 1b

2. Dynamic Experiments

The main apparatus for the air stream experiments is shown in Fig. 1a, while the necessary modifications for working in nitrogen are seen in Fig. 1b. As certain details of the procedure in the two cases differ it will be as well to describe first those items which are common to both methods.

(a) Charcoal tube: The charcoal is contained in a silica U, Fig. 2 C, fitted with glass L pieces ground at each end ($g_1 g_2, g_3 g_4$). The former fit the U by means of silica grindings surmounted by cups $W_1 W_2$ (filled with Everett's vacuum wax). The taps are well-ground vacuum taps lubricated with Ramsay grease.

(b) Evacuation of charcoal: the U containing the charcoal is heated in an electric furnace so arranged that the arms of the U project about 5 cms. from the furnace. The wax seals are protected by a thick asbestos sheet, and asbestos wool packing (*vide* Fig. 3A (e)). g_3 and g_4 fit into ground cups of the evacuation leads, and the joints are made tight by vacuum wax. The evacu-

ation outfit consisted of a Kraus mercury vapour pump backed by a Cenco Hyvac Oil Pump. Pressures are measured by means of a McLeod gauge, inserted in the evacuation lines. In most of this work two evacuation temperatures are used viz. 270°C and 800°C .

(c) Vacuum weight of charcoal: In determining this the usual precautions are taken to check the volume of the empty container by filling with mercury at a known temperature and weighing; checking for the free-space air over the charcoal which necessitated determining the density of the charcoal, reference to which will be made later, and also determining the loss in weight of the charcoal during evacuation. All weighings are carried out with a U-tube counterpoise. The weights used were checked by means of the Kohlrausch method.

(d) Saturation of charcoal with dry gas: This is carried out by attaching the U to the ground cup GS_2 Fig. 1a, allowing the contents to come to the temperature of the thermostat and then passing a stream of dry gas over the charcoal at a rate of 60-80 ccs. per min. Equilibrium being judged to be set up when the change in weight of the U was not greater than ± 0.1 mgr. Knowing the free-space volume above the charcoal a correction for the amount of gas in this was made, and hence the weight of the sorbed gas obtained.

(e) Experimental details using an air stream:

(1) Dry Air: Air from cylinder A Fig. 1a is passed through trap T_1 to the gas washer W_1 , containing conc. sulphuric acid and thence by way of flowmeter F_m to the soda lime train $S_1 S_2 S_3$ and S_4 . The rate of flow is roughly adjusted by means of the reducing valve fitted to the cylinder. and finally adjusted by taps between W_1 and A. Leaving S_4 the air passes via trap T_2 through a sulphuric acid pumice tower M, filled from F_1 , and finally, via two-way tap t_1 over phosphorus pentoxide, contained in P, into the thermostat by way of lead coil LS_2 to two-way tap t_4 ; finally issuing at GS_2 . The U is attached at this point by means of g_3 , Fig. 2c, and connected to a mercury manometer N from g_4 by means of rubber tubing. By carefully opening the container taps the flow of air is admitted to the charcoal. The manometer is used to ascertain the excess pressure, over atmospheric, of the air in the free space. Usually 2-3 mms.

Dryness of Air: In order to obtain perfectly dry air two extra gas bubblers containing conc. sulphuric acid were introduced between S_4 and T_2 Fig. 1a. To check the dryness of the air a stream at 100 cc. per min. was passed through the apparatus and thence over a weighed quantity of pure phosphorus pentoxide contained in a U-tube fitted with ground-in glass tap heads, connected of course to GS_2 . The exit side of the U was connected to an absorption bulb containing conc. sulphuric acid.

After two hours the U-tube, weighed against a counterpoise, shewed no increase in weight.

Purity of air: This was tested by attaching a small bubbling apparatus, containing lime water to GS_2 , and passing air through the train at 100 ccs. per min. for a number of hours. No precipitate of calcium carbonate was observed.

(2) Air charged with water vapour: In this case the air-stream is diverted at two-way tap t_1 via two-way t_2 through trap T_3 , containing a shallow layer of conc. sulphuric acid, into which dips a capillary inlet tube, and thence to the glass coil saturators X_1 and X_2 . These saturators are filled with sulphuric acid solutions of such strength that a water vapour pressure is obtained of approximately 1 mm. below the vapour pressure of the acid solutions of the saturators situated within the thermostat. Leaving the two "external" saturators the moist air travels through the "splash catcher" T_3 , through the lead coil LS_1 , to the "internal" glass coil saturator O_1 by way of safety trap T_4 . From O_1 the air stream passes by way of two-way tap t_3 into the "internal" saturator O_2 , and thence by way of traps T_5 and T_6 , through two-way tap t_4 to GS_2 , where it enters the charcoal tube. The two internal saturators are filled with sulphuric acid of predetermined strength to give a known water vapour pressure at 25°C .

The volumes of X_1 and X_2 are both 2000 cc., while O_1 contains 400 cc. of acid, and O_2 125 cc.

During any run with moist air the parts of the U exposed above the water level, indicated by a dotted line, are kept at $26^\circ\text{C} \pm 1^\circ\text{C}$ by means of a metal box, B, which is heated from below by means of a micro burner Q.

Efficiency of Saturators: In order to determine whether the air leaving the final saturator O_2 was saturated with respect to the solution contained therein, the amount of water sorbed by the charcoal for a given solution was determined. An additional saturator, Fig. 2D, was introduced after O_2 . The U-tube containing the evacuated charcoal, after saturation with dry air, was connected to the extra saturator and air again passed over the charcoal via the saturating train and the extra saturator. The value thus obtained for the weight of water sorbed agreed very well with the value obtained without the extra saturator.

Pressure water vapour	Mgs/grm water sorbed	
	4 saturators	5 saturators
13.40 mms	156.40	
13.36 mms		156.38

Completeness of the saturation of dry air with respect to the solution through which it passed is confirmed by the very small change in concentration of sulphuric acid after passage of air for many hours.

Run No.	Hrs. of passage of air	Concentration of Solution % H_2SO_4

	24	40.09
2	0	37.01
	25	36.99
3	0	30.94
	127	30.96

(3) Determination of water vapour pressures: The vapour pressures of the solutions were determined from a concentration-pressure curve plotted from the data of Regnault and Sorel.¹ The concentrations of the solutions were determined by means of density measurements using a 10 cc. pyknometer which was weighed against a sealed counterpoise. Two determinations for each solution being made, agreement being within 0.5 mgr. The concentrations were obtained from Domke's² figures, plotted as a concentration-density curve

(4) Possible carriage forward of sulphuric acid: Small quantities of sulphuric acid will, no doubt, be carried over to the charcoal in the course of time. To test this, a stream of air was passed through the saturators at 80 ccs. per min., and thence into a flask containing 150 cc. 1 N BaCl₂. After 5 hours a very faint turbidity was observed. A check solution containing 1.5×10^{-4} gm 98% H₂SO₄ in 150 cc. 1 N BaCl₂ gave a readily noticeable precipitate. By comparison it was estimated that the turbidity in the test run represented less than 5×10^{-5} gm H₂SO₄. This turbidity was obtained after passage of air through 61% sulphuric acid solution (the most concentrated solution used). Generally speaking, the time of streaming through the more concentrated solutions is much less than in the case of the weaker solutions. Equilibrium being more rapidly obtained at low vapour pressures than at higher ones; so that the average amount of acid carried over could not be greater than about 1×10^{-5} gm H₂SO₄ per hour. As some charcoals were exposed to various humid streams for 600 hours the maximum quantity of acid carried over would not be greater than 6×10^{-3} gm, or for a charge of 3 gms charcoal 2 mgr/gm.

(5) Changing saturating solutions: The saturators O₁ and O₂ are completely filled with the required solution from F₂ and F₃. The solutions are then drawn off through Y₁ and Y₂, well mixed and the process repeated, after which the saturators are filled to the required height. The traps T₄, T₅ and T₆ are washed, three times, by blowing over solution from O₁ and O₂, making use of soda-lime tubes Q₁ and Q₂ to prevent contamination with carbon dioxide. Withdrawal of the washings is effected via C₁ and C₂, which are finally sealed after leaving a small quantity of liquid at the bottom of T₄ and T₆.

(f) Experimental details using a nitrogen stream.

(1) Dry Nitrogen: The apparatus used in the nitrogen stream experiments is shewn in Fig. 1b. The dotted line L₁ L₁ denotes the line of demarcation to the left of which the apparatus is similar, except for a few minor details, to the air stream apparatus. Nitrogen is obtained from Cylinder A, and is 99.5% pure. The usual traps, gas washer, flow meter, and pumice-sulphuric acid tower are present. (T₁ W₁, Fm and M). T₃ is a trap while W₂ and W₃ contain conc. sulphuric acid. S₁, S₂, S₃ and S₄ constitute the sold lime train. From S₄ the dry nitrogen passes over a mixture of electrolytic

¹ Landolt-Börnstein: "Tabellen," 426-427 (1912).

² Landolt-Börnstein: "Tabellen," 265-266 (1912).

copper foil, and copper wire gauze (60 mesh) contained in two combustion tubes, CT, inserted in an electric furnace maintained at 400° - 450°C . This acts as the deoxidizer. Leaving this the gas flows through the cooling coil LS₃, and passes by way of two-way tap t_1 to the phosphorus pentoxide tube, through the thermostat, to the U tube. In order to work in as pure a nitrogen stream as possible, a special attachment to the ground joint connection GS₂ was used where by the dead space between the inserted limb of the U-tube and tap t_4 , Fig. 1a, could be evacuated and flushed out with the pure gas before it was allowed to flow over the charcoal. This procedure was carried out every time the U-tube was attached to the apparatus.

Purity of Oxygen: To test the amount of oxygen present in the gas stream, a method was worked out for the estimation of small amounts of oxygen in gaseous mixtures.¹ The point of attachment of this apparatus to the streaming apparatus is not shewn in the diagram Fig 1a.

A large number of tests were carried out on the dry nitrogen stream; results showed that the amount of oxygen present was of the order of less than 1 part in 1.5×10^5 by volume.

Dryness of Nitrogen: This was tested in exactly the same manner as in the air stream method; after 8 hours run at 80 ccs. per min. no increase in the weight of the P₂ O₅ tube could be detected.

(2) Nitrogen charged with water vapour: In this case the flow of gas is diverted at t_1 (Fig. 1b) through t_2 to the usual saturation line as shewn in Fig. 1a.

Purity of Nitrogen charged with water vapour: A few of the tests taken on the moist gas are as follows:

(1) Fresh charge of copper in deoxidizer (100 gms). Freshly made up acid. Apparatus swept out with nitrogen for 2 hours, copper not heated. After flowing for $\frac{1}{2}$ hour over copper at 400° - 450°C . Oxygen detected: 1 part in 1.4×10^4 parts N₂.

(2) Fresh charge of copper in deoxidizer. Freshly made up acid. Apparatus swept out with nitrogen for 2 hours, copper not heated. After flowing $1\frac{1}{2}$ hours over heated copper.

Oxygen detected: 1 part in 6.6×10^5 parts N₂.

Time of flow N ₂ over deoxidiser Hrs.	Oxygen detected	Rate of flow ccs./min.
100	$1/1.4 \times 10^4$	70-80
140	$1/1.4 \times 10^4$	70-80
160	$1/1.4 \times 10^4$	70-80

In many instances 100-200 hours elapsed before the charcoal reached equilibrium. To keep the oxygen concentration down to the limits found in the foregoing tests the deoxidizer was recharged every 60-100 hours. It would therefore be safe to assume that the maximum concentration of oxygen present is not greater than $1/1.4 \times 10^4$.

¹ Hand: J. Chem. Soc., 123, 2573 (1923).

(g) Record of a typical run: To obtain data to plot the results as an isotherm an experiment must be composed of a number of "runs." that is, a series of determinations of equilibrium points for various partial pressures of water vapour.

In the cases where the velocity of sorption was fairly rapid, i.e. at low pressures, the stream was passed over the charcoal until no change in the quantity of water sorbed took place over a fairly lengthy period, usually 5-7 hours. In the case of runs taking 200 hours or so equilibrium was judged when the change in weight was not greater than 0.1 mgr/gm per hour. As an example of how a "run" is carried out the following figures, taken from a trial run, will make clear the main details.

Stream:	Nitrogen—water vapour
Charcoal:	American coconut.
State of Charcoal:	As taken from stock.
Mesh size:	10-12.
Temp. of outgassing:	800°C.
Evacuated Wt. of charcoal:	1.3754 gms.
Evacuated Wt. of container + charcoal.	2.1526 gms.
Internal vol. of U-tube:	14.63 ccs.

(1) Saturation with dry Nitrogen.

1 Hrs.	2 Rate ccs/min	3 Press N ₂ mm	5 Wt. of N ₂ in free space gms.	6 Wt. of U + contents gms.	7 Wt. of N ₂ sorbed gms.

16	70	762.4	748.32	0.01544	2.5184	0.3191
22.5	60	762.0	747.92	0.01543	2.5199	0.3206

138.75 Wt. of water absorbed = 233.15 mgs/grm.

In the above table:

- Column 1 refers to the times of exposure of the charcoal to the flow of gas.
 " 2 indicates the rate of flow of the gas.
 " 3 shows the total pressure over the charcoal at the moment of detachment of the U-tube, prior to weighing.

- “ 4 gives the partial pressure of the nitrogen over the charcoal.
- “ 5 shews the weight of nitrogen + water vapour in the free space of the U-tube.
- “ 6 gives the weight of the U-tube + its contents, as weighed against its counterpoise.
- “ 7 gives the weight of water vapour sorbed by the charcoal, on the assumption that none of the gas originally present has been displaced.

FIG. 2

3. Static Experiments

(a) Charcoal tube: The container (Fig. 2B), either silica or glass, consists of a bulb 8 cc. capacity, a well-fitting end on vacuum tap, and a side tube ending in a ground joint.

(b) Vacuum weight of charcoal: The method of obtaining the evacuated weight of the charcoal is very similar to the method used in the streaming method. A more detailed account here will suffice for both methods, static and streaming.

The container, with tap in position, and shut off, is weighed, using a sealed counterpoise of the same material and having an external volume to within 1 cc. of the container. The charcoal is introduced, the tap replaced in the shut position, and the whole reweighed. Next the container tap is greased, and inserted in the shut position and the whole reweighed. An example will shew the idea of the method.

Charcoal	American Coconut
Density (after 800°C Evacuation)	1.636
Internal Volume of container No. 1 (silica)	9.929cc
1. Wt. of container + air + charcoal	= 5.2943 gms
2. " " " + air	= 2.5635 "
(1)-(2) = Approximate Wt. of Charcoal	= 2.7308 "
Volume of charcoal = 1.669 cc.	
3. Wt. of air in container	= 0.01172 gm.
T. = 17.5°C. Bar. = 740.1 mm.	
4. Wt. of air in free space above charcoal	= 0.00973 "
T. = 18.0°C. Bar = 740.1 mm.	
(1)-(4) = Wt. of container + charcoal	= 5.2846 "
(2)-(3) = " " "	= 2.5518 "
5. Unevacuated Wt. of charcoal	= 2.7328 "
After Evacuation.	
6. Wt. of container + charcoal	= 4.6502 "
(after evacuation)	
7. " " " "	= 5.3054 "
(before evacuation)	
(7)-(6) = Total loss of weight	= 0.6552 "
Wt. of air in free space	= 0.0097 "
8. Loss of wt. of charcoal	= 0.6455 "
(5)-(8) = Evacuated wt. of charcoal	= 2.0873 "

A record was kept of every evacuation regarding the loss of weight of the charcoal, in case this data should be necessary in the course of the investigation.

(c) Sorption apparatus: Shewn in Fig. 2A the apparatus consists of a reservoir R (1000 cc) connected by way of T_3 and T_8 to SP, containing a supply of water. Connexion is made to a mercury manometer M, through T_4 , and to the container S by way of T_2 , and ground-joint GS.

Connexion to the vacuum pumps is by way of

- (1) T_1 and T_6
- (2) T_5 and T_6
- (3) T_4 and T_6

Taps T_1 – T_8 are mercury sealed, the remainder are ordinary one-way vacuum taps. The whole apparatus is immersed in a thermostat, water covering the essential parts, the level is indicated by the dotted lines. The thermostat is electrically heated and maintained at $25^\circ\text{C} \pm 0.05$. The apparatus is made in one piece, excepting the container fitting, which is secured by a ground joint covered with Everett's wax and protected by insulating tape.

In all vacuum work, leaks are the chief source of error, and much unexplainable work has been too readily explained away on the grounds of leaks; at least, this is the case in the sorption of vapours by charcoal. To meet this criticism it can be said at once that in this series of work great care has been taken to reduce leakage to a minimum, by careful examination of all taps from time to time, and by testing the apparatus at very frequent intervals. Our experience has been that this apparatus can be maintained at a pressure of the order of 1×10^{-3} mm for very considerable periods, while a vacuum of 1×10^{-4} mm. can be easily held for 48 hours. As all the runs were completed in less than 24 hours the latter figure only concerns the experiments. Before commencing an experiment the water container SP is cut from the apparatus and partially filled with conductivity water. To free the water from dissolved gases, as far as possible, the upper bulb is inverted in hot water, and connexion made to a double-cylinder Geryk oil pump. Pumping is continued in stages with rests in between until the water ceases to boil, except in infrequent bursts, after this the apparatus is re-fused together.

(d) Procedure during a run: The container, with its charge of evacuated charcoal, is connected to ground cup, GS, in the manner already described and the whole apparatus exhausted to less than 1×10^{-5} mm. The water level having been adjusted, all taps are closed and a small amount of water let into the tubing below T_8 . After a short time connexion is made to an evacuated McLeod gauge, via T_7 and T_6 , in order to see if any non-condensable gases have escaped from the water. With careful manipulation fairly approximate figures can be obtained for the presence of any permanent gases. Usually a small pressure is observed, and the pumps are put on to this line for a short time. T_6 and T_7 are then closed and a small pressure of vapour admitted to R via T_3 .

Connexion is made to the charcoal by way of T_2 and the container tap. The fall in pressure is observed by taking frequent readings of the mercury levels in M by means of a cathetometer reading to 0.01 mm. and correct to 0.02 mm. This procedure is repeated until the desired pressure is reached. Equilibrium is judged when the change in pressure is not greater than 0.02 mm. per hour. At this point the container is detached and weighed. Repetition of the above procedure, admitting higher pressures of water vapour, finally brings the charcoal into contact with saturated vapour. To determine the desorption curve the charcoal is opened to decreasing vapour pressures.

4. Apparatus for collection and analysis of evolved water and gases

At the outset of this investigation it was seen that a knowledge of the water and gases given off during the evacuation of charcoal and later of the

recovery of the very strongly held water after experiments had been completed, might be of some use.

Fig. 3A shews the apparatus used. P_1 is a Toepler pump (500 cc. capacity), modified to act as a McLeod gauge. To the left of this pump is a glass vessel *a* (*vide* Fig. 3B), containing phosphorus pentoxide, connected to the leads by means of two ground joints gs_1 and gs_2 . On the right of P_1 is a smaller Toepler P_2 which is connected to a small vessel *b* (*vide* Fig. 3C). Connexion is made,

FIG. 3

by way of a third Toepler P_3 , to the gas analysis apparatus consisting of burettes B_1 and B_2 , the former having a capacity of 75 cc. and graduated in 0.1 cc., the latter 10 cc. in 0.05 cc. *A* is a combined absorption and explosion bulb¹ which is connected to the burettes by a two-way capillary tap. The phosphorus pentoxide tube Fig. 3B is so arranged as to present three surfaces of oxide to the incoming vapour. The vessel (Fig. 3C) called a "freezer" is inserted in the line by means of waxed ground joints, in cases where large quantities of water vapour are to be recovered. During an experiment this is surrounded by a mixture of ether and solid CO_2 contained in a Dewar vessel.

To carry out an experiment the phosphorus pentoxide tube is filled with about 3 gms of oxide, evacuated and weighed against a counterpoise. The

¹ Low; J. Soc. Chem. Ind., 41, 1 (1922).

"freezer" is also evacuated and weighed in the same manner. These are then inserted into their respective positions and secured by means of Everett's wax. The whole apparatus is evacuated to a low pressure (1×10^{-4} mm), t_1 shut off and the container tap T_c (static type shewn) opened to a . The temperature of the furnace is raised to the required temperature and any water vapour and gases allowed to expand into a . After a lapse of $\frac{1}{2}$ hour or so the gases are pumped off the charcoal and transferred to the gas analysis apparatus and analyzed, using the usual absorbents in A. Admission of the absorbing liquid being made by way of S.

5. The Charcoals employed

(a) Nature and condition of Charcoals: Three types of charcoals were used. (A) Air-activated birchwood charcoal of British origin which had been carbonized at 900°C and air-activated for 18 hours at $900^\circ\text{--}1050^\circ\text{C}$. (B) Zinc chloride-activated pine wood charcoal of German origin, the conditions of activation not being exactly known but believed to be prepared by treatment with ZnCl_2 , dried at $150^\circ\text{--}250^\circ\text{C}$, and carbonized at 800°C , washed and dried in vacuo at $70^\circ\text{--}80^\circ\text{C}$. (C) Steam-activated coconut charcoal of American origin, activated by the well-known Dorsey process. All charcoals, before use, were graded by sieving through a 10-mesh sieve on to a 12-mesh sieve. The charcoal retained by the latter sieve being used for the experiments.

(b) Analysis of charcoals: The question of the inorganic constituents of charcoal, and its effect on the sorption process being a somewhat debatable question, when this work was commenced it was decided to analyse the charcoals used. The following results were obtained. They are expressed as percentages of the dried charcoal (dried at $140^\circ\text{--}150^\circ\text{C}$ to constant weight).

		British	American	German
Silica an insoluble material		1.22	1.03	0.55
Zn expressed as ZnO				1.43
Al	" " Al_2O_3	0.47	0.26	0.12
Fe	" " FeO	0.34	0.06	0.89
Mn	" " MnO	0.07	0.007	0.016
Ca	" " CaO	1.097	0.245	0.22
M	" " MgO	0.207	0.087	0.02
Na	" " Na_2O	0.257	0.195	0.07
K	" " K_2O	0.30	0.90	0.726
Alkalinity	" " CO_2	0.02	0.40	
SO_3	" "	0.197	0.057	0.503
S		0.104	0.026	0.081
Cl	" "	0.207	0.093	0.422
P_2O_5	" "	0.134	0.075	0.029

The ash content of each charcoal was determined in the usual manner using a gas-fired muffle furnace. Expressed as percentages of the dried material the results are as follows:

British	American	German
4.59	2.20	3.90

During the evacuation of the charcoals it was believed that a small amount of material, which we termed "sublimate" was laid down on the cold portions of the silica containers. In the case of the British and American charcoals this "sublimate" made its appearance when the charcoals were heated to 800°C and consisted of a narrow band of material, which by reflected light was very similar in appearance to the well-known arsenic mirror deposits. In the case of the German charcoal a small amount of "sublimate" was formed at 270°C and a large quantity at 800°C . This was grayish in colour and formed in wider bands than in the case of the other charcoals. We thought it of sufficient interest to analyse these "sublimates." To do this a special silica container was employed holding about 5–6 gms. of charcoal. To obtain this sublimate the charcoals were outgassed for a considerable period at 800°C until we were certain that no more volatile condensable matter was being evolved. The results of the analysis of the sublimates are as follows (expressed as percentages of the dried charcoals).

	British	American	German
Free Na	0.003	0.003	
Combined Na	0.13	0.05	0.27
" K	0.10	0.05	0.28
Cl	0.24	0.00	0.49
SO ₄	0.20	0.01	0.006
Zn			0.725
Mn			0.05
Fe			0.03

(c) Extraction of charcoals with acid and alkali: In order to investigate the effect of the reduction of the inorganic constituents of the charcoals, two methods of extraction were used.

(1) Acid extraction: In this method batches of charcoal were boiled with concentrated hydrochloric acid for 8–9 hours, renewing the acid lost by evaporation from time to time. The acid was then decanted off and the charcoal transferred to a special glass percolator, where distilled water at about 90°C was allowed to flow through the charcoal until the wash liquid no longer gave a turbidity when tested with 10% silver nitrate solution. The ash content of the charcoals so treated was as follows.

British	American	German
0.31	1.34	0.12

(2) Alkali extraction: Two methods were used, one in which the charcoals were extracted by heating with concentrated caustic soda at atmospheric pressure, the other in which the extraction was carried out under pressure in an autoclave.

Extraction at atmosphere pressure. 100 gms of charcoal was treated with a solution of caustic soda containing 100 gms NaOH. The whole was digested for 7 hours, taking almost to dryness several times. The charcoal was then washed as free from NaOH as possible, digested with concentrated hydrochloric acid for 6 hours, and then washed until the wash liquid gave no reaction with silver nitrate solution. The above process was repeated and the charcoal finally dried at 150°C to constant weight. After this treatment the charcoals gave the following ash figures.

British	American	German
0.295	0.125	0.14

In the case of the American extracted charcoal, a further attempt was made to reduce the ash content by digesting with hydrofluoric acid. The resulting material gave an ash content of 0.10%. In the case of the British charcoal a quantity of ash was prepared and examined both chemically and microscopically. By the latter method it was generally agreed that the substance was almost wholly aluminum silicate. Analysis revealed positive tests for aluminum and silica.

Extraction under pressure. These experiments were unsuccessful as it was found very difficult to free the charcoal from alkali after the extraction had been carried out, presumably owing to the innermost pores of the material having been filled with the solution.

(d) Microscopic and X-ray Examination of Charcoals: Sections of the charcoal were prepared and microphotographs at 100–150 diameters magnification obtained. The results did not hold out much promise of giving very useful information, so the preparation of sections for examination at higher magnifications was not proceed with. Two papers¹ have appeared in which the subject of the microstructure of activated charcoals has been, to some extent, dealt with.

With regard to X-ray work, the charcoals were examined by both the photographic and ionization methods. The results are quite inconclusive, beyond shewing that these activated charcoals are composed of a mixture of graphite crystals and irregularly arranged carbon atoms.

(e) Density of Charcoals: Using a "static" container the charcoal was weighed out in the usual manner and outgassed at either 270°C or 800°C. After cooling and weighing, the L piece of the container was filled with distilled water (25°C) and dipped under the surface of distilled water. The water was admitted to the charcoal by carefully opening the container tap, which was closed after complete entry of water had been effected. The container was then weighed, after removal of all external water. Knowing the volume of container, its weight and also the weight of the container + charcoal, and the weight of the container + charcoal + water, the volume of the charcoal was obtained and hence its density. No claim is made for these de-

¹ Harkins and Ewing: J. Am. Chem. Soc., 43, 1787 (1921); Lamb, Wilson and Chaney: J. Ind. Eng. Chem., 11, 420 (1919).

terminations to represent the true density as "drift" was not allowed to complete itself. The figure for the volume of charcoal will be somewhere between the apparent bulk volume and the true volume.

The results obtained are as follows:—

	Evacuation temperature	Density
British	270°C	1.880
	800°C	1.715
American	270°C	1.797
	800°C	1.636
American Extracted (NaOH & HCl)	800°C	1.618
German	270°C	1.678

6. Summary

In the foregoing paper the following have been described:

(1) Apparatus for carrying out sorption and desorption of water vapour by charcoal by both a "static" and dynamic method.

(2) Apparatus for the recovery, from charcoal, of the sorbed water vapour and gases.

(3) The results of the analysis of the inorganic constituents of three well-known charcoals, including examination of "sublimates" formed during outgassing.

(4) Reference to microscopic and X-ray examination of these charcoals, together with details of extraction of the charcoals by both acid and alkali.

In conclusion it remains for the authors to express their appreciation of the assistance rendered by Professor Allmand, during this work, and to thank those colleagues who assisted in this work.

CATALYTIC ACTIVITY OF THALLIUM

BY O. W. BROWN, CHESTER BROTHERS AND G. ETZEL

Introduction

Thallium is an active hydrogenation catalyst¹ and it is one of the **three** that give high yields of azobenzene. The activity of thallium decreases **very** rapidly with use. This decrease is probably caused by the melting and **running** together of the catalyst.

Some catalysts, such as lead and bismuth, may be used at temperatures considerably above their melting points without undergoing any appreciable change in their physical condition. In the case of lead, however, it was found that some lead catalysts ran together while others did not, depending, to a certain extent, upon the physical properties of the oxides from which the catalysts were made. In view of the above, it was thought that a solid support might be found for a thallium catalyst that would adsorb the catalyst without reducing its activity, and thereby prevent it sintering. If sintering was prevented, the useful life of the catalyst would be prolonged.

Experimental Work and Results

The apparatus, method of work, as well as the purification of thallium, were the same as those previously described.² In this investigation, however, the catalyst tube used was a one-half inch diameter glass combustion tube. Three catalysts were prepared from precipitated thallic hydroxide; one was ignited in an electric muffle for two hours at 500°C., and the other at 300°C., while another portion was not ignited. All three were reduced at 230°C. for 3 hours, with the rate of flow of hydrogen of 2 liters per hour. As may be seen in the work referred to above, the temperature at the point where reduction takes place was much higher than at any other part of the catalyst column. In order to keep the temperature as uniform as possible throughout the furnace, the flow of hydrogen was kept low. In spite of this precaution, the catalyst, after reduction, was found to contain globules of massive thallium, showing that it had partially melted and run together. Thus, it may be concluded that an ignited thallium oxide will not give a catalyst which will not melt. In an effort to find a catalyst which could be used satisfactorily without running together, solid supports for thallium were tried. The first of these was aluminum hydroxide, mixed with about 12.8% of metallic thallium. This mixture was prepared as follows: sulfates of thallium and aluminum were mixed and precipitated with ammonium hydroxide. The precipitated hydroxides were thoroughly washed by decantation, filtered, dried, and ground in a mortar to a fine powder. About 25 g. of this powder, which had a light brown color was used to make a catalyst. It was reduced for 3 hours at 230°C., the

¹ Henke and Brown: J. Phys. Chem., 26, 631 (1922).

² Henke and Brown: J. Phys. Chem., 26, 631 (1922).

rate of flow of hydrogen being 2 liters per hr. The catalyst was then used at 245°C. with a resulting yield of 1.7% aniline. At 300°C. the yield of aniline was 5.5%, and at 400°C. was 14.9%. At 400°C. there was also a trace of azobenzene produced. As is evident from the data given, this catalyst was very inactive. However, it appeared to be in good physical condition; it was black and without lustre.

The solid supports next tried were pumice and Nonpareil brick, which were crushed and passed through a 10-mesh sieve, and remained on a 20-mesh sieve. In each case the support was cleaned by boiling in nitric acid, washed with distilled water, and then ignited at 500°C. Each of these were immersed in a thallic sulfate solution, placed in a vacuum desiccator, and evacuated 7 times. The purpose of this was to replace the air in the pores of the support by the thallic sulfate solution. The supernatant thallic sulfate was then poured off and ammonium hydroxide added to the support, which was soaked full of thallic sulfate solution. This precipitated thallic hydroxide in the pores and on the surface of the supports. Each impregnated support was then filtered, washed, and allowed to dry at room temperature.

Thallium on pumice catalyst was used in six experiments at temperatures ranging from 230°C. to 300°C. The rate of nitrobenzene was 4 g. per hr. and of hydrogen 7 liters per hr. No appreciable amount of azobenzene was secured in any experiment. The highest aniline yield was 6.25% at 300°C. This indicates that thallium on pumice is a poor catalyst.

Thallium on Nonpareil brick was used at 245, 260 and 275°C. with the rate of flow of hydrogen at 7 liters per hr. and the rate of flow of nitrobenzene at 4 g. per hr. No appreciable amount of azobenzene was secured. The aniline yield was 6.6% at 275°C., which was the highest yield secured.

Asbestos was the last of the solid supports tried. It was boiled with nitric acid, washed, dried, soaked in thallic sulfate solution, desiccated, and treated with ammonim hydroxide. The catalyst prepared consisted of 24 g. of thal-

TABLE I
Catalyst—Thallium on asbestos
Rate of flow of nitrobenzene—4g. per hr.

Temperature degrees C.	Flow of hydrogen in liters per hr.	Excess of hydrogen based on azobenzene in per cent of theory	Material yield in per cent of theory		
			Aniline	Azobenzene	Total
230	7	360	9.6	15.2	24.8
245	7	360	10.7	70.9	81.6
260	7	360	16.	83.7	99.7
260	14	820	12.6	83.9	96.5
260	7	360	14.1	79.0	93.1
245	7	360	8.4	78.2	86.6
245	14	820	4.3	81.2	85.4
260	14	820	9.5	82.0	91.5
260	14	820	11.8	75.5	87.3
260	14	820	7.8	74.8	82.6

lithium on 9 g. of asbestos. In order to determine the best working conditions experiments were made at different temperatures and at different rates of flow of hydrogen. The results of these experiments are given in Table I. The yields given are averages of from 2 to 12 experiments.

From Table I it can be seen that the best yields of azobenzene and aniline were obtained at 260°C. The rate of flow of hydrogen which gave the highest yield was 14 liters per hour for azobenzene, and 7 liters per hour for aniline. It may be concluded, therefore, that the best yields of azobenzene are obtained at a temperature of 260°C., and with a rate of flow of hydrogen 14 liters per hour. The activity of the catalyst decreased slightly at first, but after 56 runs it became constant. When temperatures as high as 275 to 280°C. were used the yields of azobenzene were 77 to 75%.

Experiments were also made in this laboratory by Dr. C. O. Henke and E. D. Scudder using a 1½ inch vertical tube iron furnace 12 inches long. The catalyst used contained 60% Tl_2O_3 . The yields obtained were from 85 to 90% theory azobenzene. The production of azobenzene amounted to more than 150 times the weight of thallium in the catalyst before rejuvenation was necessary.

All catalysts tried on solid supports were in good physical condition after being used. The adsorption of thallium by the support was efficient in preventing it from melting and running together, although in the case of aluminum, pumice and Nonpareil brick their presence have reduced the adsorption of hydrogen and nitrobenzene to such an extent as to produce very poor catalysts. Asbestos not only adsorbs thallium preventing its running together, but also does not interfere with the adsorption by thallium of hydrogen and nitrobenzene, resulting in good yields of azobenzene and long life of the catalyst.

Summary

1. Finely divided metallic thallium melts and runs together when used as a catalyst, resulting in a loss of its activity.
2. Thallium on asbestos is an excellent catalyst for the production of azobenzene, and the catalyst retains its activity for a comparatively long period of time.
3. A temperature of about 260° C. gives the highest yields of azobenzene.

A COMBINED CAPILLARIMETER-VISCOMETER

BY S. THOMAS BOWDEN

The practical determination of the physical constants of organic and also inorganic liquids has been accorded a considerable amount of attention of late, in view of several recent theories which aim at satisfactory and comprehensive correlation of physical properties with chemical constitution. Similar remarks apply to recent studies of solutions, and in this connexion, it is evident that a systematic extension of our knowledge of the physical properties of solutions is necessary in order to effect a reconciliation between the several existing theories. Among these properties, those of surface tension and viscosity have been brought into especial prominence both in the case of pure liquids and solutions.

In general, the determination of the surface tension and viscosity of a liquid involves the use of separate apparatus in each case. As a result of work proceeding in this laboratory an apparatus has been designed by means of which the determination of the density, surface tension and viscosity may be carried out conveniently and rigidly.

It has been shown by Richards and Combs¹ and Richards and Carver² that the capillary-rise method for the determination of surface tension is entirely reliable when adequate experimental precautions are observed. Accordingly, the present apparatus embodies the principle developed in the Richards capillarimeter, and is of such dimensions that an experimentally plane surface of reference is realized. For the measurement of the viscosity the relative viscometer principle is utilized, and the arrangement is an adaptation of the well-known Ostwald viscometer.

Description of Apparatus.—A diagram of the apparatus is shown in Fig. 1 (a). *A* is a wide tube 5.5 cm. long and 3.8 cm. in diameter, to the lower end of which is fused a bulb, *B*, upon which is etched a mark, m_1 . Ordinary quill tubing, 4 mm. in diameter, connects the wide tube, *A*, to the capillary tube, *C*, in such a way that the lower end of the capillary tube is above the etched mark, m_1 , on the bulb, *B*. The capillary tube is carefully selected for uniformity of bore as measured by the usual mercury thread method. In the present apparatus the internal diameter of the capillary tube is approximately 0.5 mm. It is 7 cm. in length, and is arranged parallel to the longitudinal axis of the wider tube, *A*. The upper end of the capillary tube joins to a spherical bulb, diameter 1.5 cm., provided with etched marks m_2 , m_3 above and below. On the other limb, *E*, immediately opposite the lower mark, m_3 , of the bulb, *D*, is a constriction upon which is etched a mark, m_4 . The upper part of the tube, *E*, is closed by a well-ground three-way hollow stopcock, *S*, open at the bottom, a cross-sectional view of which is shown in Fig. 1 (b). In the first

¹ J. Am. Chem. Soc., 37, 1656 (1915).

² J. Am. Chem. Soc., 43, 827 (1921).

position, shown in Fig. 1 (a) and Fig. 1 (b), the stopcock provides communication (via the tube, *H*) between the tubes, *G* and *F*, as well as between both limbs of the apparatus. By turning the stopcock through 90° in an anti-clockwise direction, the two limbs of the apparatus are in communication, via the tube, *H*, with *G* only. On the other hand, if the stopcock is turned through 90° in a clockwise direction from the position shown in the diagram, communication between *F* and *G* can only be effected through the system *EAB-CD*. The stopcock is lubricated with the liquid under investigation.

The short tubes, *F* and *G* possess tapering ends, equipped with well-ground glass caps, whilst the tube, *H*, 1.6 cm. in length, joins the limb *EAB* to *CD*. The over-all length of the apparatus is about 15 cm.

When only a small amount of liquid is available for the determinations, the working volume of the apparatus may be reduced by the introduction of a hollow glass sinker of the form shown in the diagram. This may be conveniently weighted by means of mercury. The underside of the sinker, *W*, is provided with three short projections in order to ensure a free passage of gas through the apparatus during the viscosity determination. Furthermore, in the measurement of the surface tension, it is desirable to arrange the plane reference surface of the liquid approximately half-way in the wide tube, *A*, and, accordingly, the height of the sinker should not exceed this distance.

When the quantity of available liquid is very small, it is advisable to determine the density in a separate pyknometer. In these circumstances, 10 cc. of liquid suffices for the determination of the surface tension and viscosity.

As is customary in surface tension measurements, the capillary tube is calibrated by means of a mercury thread, the length of which is measured along the capillary by means of a travelling microscope.

Manipulation of Apparatus.—It has been shown by Harkins and Brown¹ that steaming out the capillary tube before a determination brings about a slightly higher capillary rise. With organic liquids, however, the difference is found to be extremely slight. Accordingly, a thorough cleaning of the apparatus by means of warm chromic acid solution followed by rigorous washing with water and a final drying in a current of pure dry air is the procedure which we adopt at present.

¹ J. Am. Chem. Soc., 41, 499 (1919).

FIG. 1

The liquid under investigation is introduced into the apparatus through *G* by applying gentle suction at *F*, the stopcock being arranged for communication of the limbs *GDC* and *AEF*. Sufficient liquid is introduced to fill both limbs up to the etched marks, *m*₃, *m*₄. The apparatus is immersed in a carefully regulated thermostat, and the level of the liquid adjusted for coincidence with the etched marks by means of a fine capillary tube. The apparatus is then removed, dried and weighed. A preliminary determination with water or any other standard liquid affords the necessary data for the calculation of the density.

A portion of the liquid is next removed through the tube, *G*, so that the liquid surface occupies a roughly central position in the wide tube, *A*. The apparatus is then set vertically in a thermostat provided with glass sides. After ensuring complete wetting of the tube in the neighbourhood of the meniscus, the capillary rise is measured in the usual manner by means of a cathetometer. In the present apparatus, since the capillary employed is small, the corrected height, *h*, according to the equation of Hagen and Desains,¹ becomes

$$h = h_1 + \frac{h_m}{3} = h_1 + \frac{r}{3} \cdot \text{(when } r \text{ is small)}$$

where *h*₁ is the observed height, and *h*_m is the height of the capillary meniscus. In this manner, the application of the usual formula enables us to calculate the value of the surface tension.

For the purpose of the viscosity determination, a further quantity of the liquid is removed through the tube, *G*, until the liquid surface reaches the etched mark, *m*₁, on the bulb, *B*. The apparatus is arranged vertically in the thermostat, and liquid drawn up to fill the upper bulb, *B*, by applying gentle suction at the end of the tube, *G*. The ground caps are quickly replaced and the stopcock set for communication of the two limbs via the tube, *H*. The time of flow of the liquid between the etched marks, *m*₂ and *m*₃, is observed by means of a stop-watch. The water constant of the apparatus is known from a preliminary determination, and the relative viscosity may be calculated by the usual methods. In this connexion, however, it is advisable, in order to ensure greatest accuracy, to redetermine the water constant of the apparatus from time to time. Owing to inherent errors in the Ostwald type of apparatus, it follows that the degree of precision attainable is considerably below that realized in the measurement of surface tension.

It will be evident that the present apparatus lends itself to the determination of surface tension and viscosity under a variety of conditions. In the case of hygroscopic substances, measurements may be carried out in an atmosphere of dry air, the gas being passed very slowly through the tube, *G*, with the stopcock arranged for communication between *H* and *F*. Incidentally, the apparatus is well adapted for carrying out measurements on reactive substances, such as free radical solutions, dry nitrogen being employed as inert

¹ Ann. Chim. Phys., (3) 51, 417 (1857).

atmosphere in these cases. The combined form of apparatus possesses the further advantage that the measurements are made conveniently and rapidly on the same sample, and that the total volume of liquid required for the determination of the three quantities, density, surface tension, and viscosity, is considerably less than that necessary when the same constants are determined in separate apparatus.

NITROGEN-OXYGEN-NITROGEN OXIDE EQUILIBRIA

BY NORMAN W. KRASE*

The investigation into the chemical equilibrium involving the formation of nitric oxide from its elements at high temperatures is a problem that interests both scientific and technical workers. As an example of a pure thermal equilibrium it has been used in the study of rates of reaction and the change of equilibrium with the temperature. Its technical interest arises from the fact that it is one of the oldest processes for the fixation of atmospheric nitrogen. In point of time perhaps it is one of the oldest chemical reactions which still retain modern industrial significance.

The present article is a by-product of an investigation into novel methods of nitrogen fixation.¹ This investigation was based entirely upon published results and involves merely the use of simple physical chemical and thermodynamic principles in arriving at data applicable in new reactions. Since the formation of nitrogen oxides is concerned in one prominent fixation process and in the oxidation of ammonia it is of importance to explore thoroughly the accuracy of the methods on which the principle data are based. Up to the present time the data of Nernst² on the nitric oxide equilibrium have been regarded as classic. The data were obtained by Nernst and his coworkers by heating air to high temperatures, suddenly cooling the gas, and analyzing for nitric oxide by absorbing the products in sulfuric acid. The data so obtained have served as a basis for most calculations involving dependent equilibria. It is significant that the present arc process for the fixation of nitrogen used in Norway appears to substantiate the results of Nernst in regard to yields. In the book of Lewis and Randall³ the various equilibria involving nitrogen and oxygen have been thoroughly analyzed and summarized. The foundation of all the calculations is the data of Nernst and on these data have been erected a large body of related results. For example a very important conclusion, the free energy of formation of nitric oxide from its elements, has been derived. This equation is the following:

$$\Delta F^{\circ} = 21600 - 2.50T$$

A casual inspection of the book will make it evident that the accuracy and dependability of perhaps a dozen calculations are involved in the accuracy of this equation.

Very recently an article has appeared in a French journal⁴ entitled "On the Formation of the Oxide of Nitrogen at High Temperatures," by Briner,

* Chemistry Dept. Univ. of Illinois.

¹ Published by permission of the editor of the A. C. S. Technologic Series of Monographs. This material is part of the forthcoming monograph on "Nitrogen Fixation" by H. A. Curtis and N. W. Krase.

² Z. anorg. Chem., **49**, 213 (1906).

³ "Thermodynamics."

⁴ J. Chim. phys., **23**, 788-807 (1926).

Boner, and Rothen. These investigators have reopened the apparently closed question of the nitric oxide equilibrium and have published new experimental results. They point out that the old results of Nernst are subject to at least two errors. First of all, because of the speed of reaction it is entirely probable that the nitrogen oxide formed at a high temperature will decompose very rapidly on leaving the heated zone. They state that this effect is considerable under the conditions used by Nernst. Secondly they point out that the analytical method involved in determining the yield of nitric oxide is unreliable, substantiating that statement by reference to other work in which it is shown that only an incomplete absorption of nitrogen oxides can be obtained by bubbling the gas through sulfuric acid. The equilibrium was re-investigated with improved technique. For example, the gas leaving the heated zone was aspirated very rapidly into a balloon reservoir and left in contact with strong potassium hydroxide for one day. The nitrates and nitrites formed on absorption were then reduced and the ammonia distilled off for titration in dilute acid. In this way the authors claim to be able to determine .002 cc. of nitric oxide. Table I gives the results of the two investigations just briefly described. They were obtained in both cases by heating air to the temperatures indicated.

TABLE I

T	Nernst	Per cent NO	Briner
1500	—		.19
1811	.37		.65
2195	.97		1.86
2580	2.05		3.89
2675	2.23		—

It is obvious from this table that the new concentrations of Briner are approximately 100% greater than those of Nernst. If we accept the validity of these new results it is of interest to calculate the corresponding free energy of formation and also the effect of the new data on many other important equilibria. This has been done and the new equation based entirely on Briner's data is as follows:

$$\Delta F^{\circ} = 21600 - 3.70T$$

Since it was found that the heat of the reaction as determined by plotting $-R \ln K$ against $1/T$ gave substantially the same value as used by Lewis and Randall in the formulation of their equation, merely a new constant has been calculated.

The free energy of formation of the oxides of nitrogen depends very considerably upon the free energy of formation adopted for nitric oxide. The corresponding thermodynamic quantity for nitric acid likewise depends on the value ascribed to nitric oxide. Table II lists in parallel columns the old free energy values given by Lewis and Randall and the new values calculated on the basis of Briner's data.

TABLE II

Compound	ΔF°_{298}	
	Lewis and Randall	Recalculated
NO (g)	+20850	+20500
NO ₂ (g)	+11920	+11570
N ₂ O ₄ (g)	+22640	+21900
HNO ₃ (g)	-18210	-18560

It is seen that the change involved is of the order of 2 to 3%. This in many cases makes a very large difference in the concentrations obtainable at equilibrium.

Summary

The free energy of formation of nitric oxide from its elements has been recalculated on the basis of the latest published data. A new equation expressing the relation between the free energy of formation and the temperature has been developed. The importance of this relationship in many other equilibria has been emphasized.

THE EQUILIBRIUM (POLARIZATION) COMPOSITION OF THE LIQUID SALT PHASE AND THE LIQUID ALLOY PHASE IN A SYSTEM COMPOSED OF EQUIATOMIC QUANTITIES OF SODIUM, POTASSIUM, AND IODINE

BY HERBERT F. SILL

Recent studies by Lorenz, Fraenkel and Silberstein¹ and by Tammann and Bohner² contain data showing the equilibrium distribution of the elementary components in the following two-liquid-phase, three-component systems.

Cadmium-lead-chlorine

Cadmium-thallium-chlorine

Iron-copper-sulphur

In the first of these systems both metallic components are divalent, replacing one another atom for atom. In the second and third systems one is di-valent and the other monovalent. The system here presented constitutes an extension of the list to include a system in which both components are monovalent.

The data for the first two systems extend over a wide range of variation in the atomic proportions of the three elements present and the phase compositions corresponding either to equiatomic or to chemically equivalent proportions can be accurately interpolated. The data for the iron-copper-sulphur system apply only to the case in which the components are present in chemically equivalent proportions, i.e. in the atomic proportion of 1:2:1.

The system sodium-potassium-iodine.

Materials. (a) Sodium and Potassium Iodides. A quantity of c.p. salt (Merck) was in each case fused in a platinum dish and on solidifying was ground and preserved over P_2O_5 .

(b) Sodium metal. Commercial sodium analysing 97.2% Na was distilled in hydrogen, a wide-bottomed Erlenmeyer flask being used as a receiver. A part of the kerosene in which the commercial metal had been preserved was transferred to the receiver and the latter warmed on a hot-plate until the metal melted and formed a shallow layer beneath the kerosene. By gently shaking the metal was caused to separate into large globules which presently solidified. The kerosene was decanted and the globules washed by repeated decanting with Na-dried petroleum ether B.Pt. 75° the final addition of petroleum ether being left in the flask.

(c) Potassium metal. Globules were prepared directly from the laboratory supply without distilling. The procedure was otherwise the same as that employed for the sodium.

¹ Z. anorg. Chem., 131, 247 (1923).

² Z. anorg. Chem., 135, 166 (1924).

The method and numerical result of the analysis of the two metals is given below in connection with the analysis of the equilibrium alloys.

Containers. Pieces of soft steel tubing 15 cm. long and 15 mm. inside and 20 mm. outside diameter were brightly polished within and without and at each end the bore of the tube was slightly enlarged for a distance of one cm. The tube, supported in a clamp, was submerged over four-fifths of its

FIG. 1

length in a pail of water leaving 3 cm. exposed. A tightly fitting steel plug was placed in the upper end and sealed in with an oxy-acetylene torch. On connecting it with a manometer and evacuating the seal was found to be tight.

Charging the tube. Two large sodium globules which had remained bright and untarnished in the petroleum ether were taken up with a forceps, dipped in Na-dried ethyl ether and transferred to a vacuum weighing-tube. The latter was evacuated to remove the ether and the weight of the metal determined. An amount of potassium iodide chemically equivalent to the sodium was weighed out, dried air was admitted to the vacuum-tube and the metal globules transferred to the steel tube followed by the weighed portion of the salt. The mouth of the tube was closed with a steel plug and sealed as before.

Heating. An electric tube-furnace was used for heating the reaction materials. The furnace-tube employed was a 60 cm. length of steel tubing of 3 cm. bore. This tube was inserted horizontally through the furnace opening and attached at one end to a geared motor. The other end was supported in a semicircular bearing cut in piece of graphite plate. An ammeter was

placed in the heating circuit and a thermo-couple inserted axially in the furnace-tube. The tube was then rotated at 70 R.P.M. and the current required to maintain a constant temperature of 700° and 725° respectively was determined.

The thermo-couple was put aside and the furnace-tube taken from the furnace and allowed to cool. The sealed reaction-tube was now placed within the furnace tube and secured in a slanted position by means of a plug of heavy steel turnings rammed in from each end and the whole replaced within the furnace and rotated as before for ten minutes at 725° and for fifty minutes at 700° .

The volume of liquid material within the reaction-tube could be calculated to occupy about half the available space. The effect of the rotation and the gravity movement due to the inclined position of the reaction-tube would be a somewhat spiral flow back and forth with each revolution.

The furnace-tube was disconnected from the motor, and tube and furnace together were turned to a vertical position, the heating current being meanwhile continued. The tube was raised and allowed to drop repeatedly on a steel block placed below, in order to promote the complete coalescence and segregation of the material belonging to each liquid phase. It was then removed from the furnace and allowed to cool.

The reaction-tube was extracted from the furnace-tube and placed upright in a vise. The upper end of the tube was then removed with a pipe-cutter and the tube at once filled with Na-dried kerosene. The bright surface of the solid alloy could be seen below. The alloy was melted by dipping the tube in hot kerosene and the liquid contents of the tube, viz. kerosene and alloy, were decanted into a small flask containing additional hot kerosene. The metal, which coalesced to form a single large globule was allowed to solidify, rinsed successively with petroleum ether and ethyl ether and transferred to the vacuum weighing-tube and the weight obtained.

The weighed globule was transferred to a platinum dish and placed together with a beaker of water under a bell-jar.

The resulting syrupy hydroxide solution was diluted and aliquot portions titrated with $n/5$ HCl. Here the requirements of precision analysis were carefully observed, the volumetric glassware having been standardized by weight and the normality of the acid determined against anhydrous sodium carbonate.

A weighed globule of the distilled sodium-metal used as initial material was treated and analysed in the same manner, the calculation yielding the value 100.05% Na.

The reverse reaction was now carried out in a second reaction-tube charged with chemically equivalent quantities of potassium-metal and sodium iodide, the same conditions as to time, temperature and manipulation being observed throughout.

The titration analysis of the initial potassium-metal gave the value 99.85% K.

For each of the alloy globules the titration gave the sum (s) of the gram-atoms of sodium and potassium therein contained. From this value and its weight in grams (w) the number of gram-atoms of sodium (x) and the number of gram atoms of potassium (s-x) are calculated from the equation $23x$ plus $39.1(s-x) = w$.

The experimental data and the derived values are contained in the following table:

initial reacting sub- stances	weight of alloy (w)	total gram- atoms (s)	gram- atoms sodium (x)	gram- atoms potass. (s-x)	atomic ratio Na:K
Na & KI	.7607	.03138	.02896	.00342	11:1
K & NaI	.4456	.01804	.01615	.00189	9:1

The difference in composition of the two "equilibrium alloys" can not be assigned to analytical error and since the equilibrium was approached from each side under identical conditions of temperature and of rate and duration of mechanical agitation the true value for the equilibrium atomic ratio Na:K in the alloy may be placed half-way between the above values or at 10:1.

The direction of the divergence from the true value is, for the two incomplete reactions, what would be expected. Where sodium constituted the initial reacting metal its preponderance in the alloy is greater than where all the sodium appearing in the alloy had to be derived by displacement from the compound.

Jellinek and Czerwinski¹ and Jellinek and Tomoff² determined the equilibrium ratios Na:K and KCl:NaCl for a system in which a lead solution of the alkali metals and a fused chloride mixture constituted the respective liquid phases. Owing to the relatively "noble" character of the lead the electrolyte phase consisted virtually of the alkali chlorides only. The determinations involved the initial reacting substances in widely varying proportions and were conducted at a temperature of 1000 degrees.

Their results are given in the following table.

Na:K	KCl:NaCl
17.0	.87
12.5	1.04
5.25	2.12
4.30	2.63
1.50	6.94
.725	12.35

The same relationships had been previously determined by G. M. Smith and T. R. Ball³ for a system in which a dilute solution of the alkali metals in mercury formed the metal phase and a water solution of the chlorides the elec-

¹ Z. physik. Chem., 110, 172 (1924).

² Z. physik. Chem., 111, 234 (1924).

³ J. Am. Chem. Soc., 39, 179 (1917).

trolyte phase. Here likewise the "noble" metallic component was virtually present in the metal phase only.

In the system of Jellinek et. al. the *total* salt concentration in the fused salt mixture comprising the electrolyte phase remained essentially constant throughout the wide range of variation in the salt *ratio* KCl:NaCl.

In the Smith and Ball system, owing to the presence of water as the chief constituent of the electrolyte phase, the total salt concentration could also be widely varied.

In the diagram the point F represents the result of the investigation previously described for a system composed of equiatomic quantities of sodium, potassium and iodine. This system contained no "solvent" water in the electrolyte phase nor "solvent" noble metal in the metallic phase. The curve 3 represents the Jellinek data, i.e. for a system containing "solvent" lead in the metal phase and chlorine instead of iodine in the electrolyte phase. The curves cutting the diagonal at B and A represent respectively Smith and Ball data for systems of 4.0 normal and of 2/10 normal total salt concentration, i.e. for a system containing a diluent in both phases.

The intersection of each curve with the diagonal of the diagram represents the reciprocal relationship Na:K in the metal phase and K:Na in the electrolyte phase when the components sodium, potassium and halogen are present in the system in equiatomic quantity. The curve 5 represents the system cadmium-lead-chlorine and the curve 4 the same active components with the addition of the relatively "noble" (inactive) metallic component antimony. The intersection of each of these two curves with the diagonal gives the atomic ratio Pb:Cd and Cd:Pb when these two components are present in the system in equiatomic quantity.

A comparison of the points F, C and B shows that so far as composition changes are concerned, the combined effect of replacing the iodine by the more electro-negative chlorine and of dissolving the alkali-metal binary alloy in the less electro-positive lead has been to reduce the equilibrium atomic ratio from 10 to 3.4 and that the combined effect of a further substitution of the "solvent" lead by the still less electro-positive (nobler) mercury and the introduction of "solvent" water has been to further reduce the ratio to the value 1.5.

NEW BOOKS

A Dictionary of Applied Chemistry. Vol. VII. By Sir Edward Thorpe. 22 × 15 cm.; pp. viii + 576. New York and London: Longmans, Green and Co., 1927. Price: \$20.00. This is the seventh and last volume of this impressive set. Among the interesting topics in this section of the alphabet are thallium, theine, thermometers, thermostats, thiophen, thorium, thyroid gland, tin, titanium, tobacco, toluene (84 pp.), toxins, triphenylmethane coloring matters, tropeines, tryptophan, tungsten, turpentine, tyrosine, ultramarine, uranium, urea and urine, vanadium, vanillin, varnish, vat dyes, vitamins, water (106 pp.), wax, whiskey, wine, destructive distillation of wood, xylenes, yeast, yttrium, zinc, zirconium.

"The fact that theine (caffeine) exists in the leaves of the coffee plant has long been known, but it is only since the war that they have been commercially exploited to produce this drug. The idea originated in Sumatra, where, under the present system of cultivation, coffee is frequently attacked by insects of the genus *coccus*. With the failure of the berry drop, the growers, seeking a substitute for the ordinary caffeine-containing product, collected the leaves from which pure theine was prepared. With the war the demand for theine so greatly expanded that the process of extracting it from the leaves was resorted to on an extensive scale by the Dutch factories, which purchased them by the ton from the native growers and pickers. So far, the process of preparation has been kept secret, but there is no gainsaying the purity of the product. On the western side of the island of Sumatra the producers, and, in fact, the general public, have long used an infusion of torrefied coffee leaves as a beverage, the berries themselves all being reserved for export. The use of the leaves for this purpose has grown to such an extent that it is now looked upon as an absolute necessary of life.

"During the past four years Germany has been importing enormous quantities of coffee leaves from Sumatra and utilizing them in the same way; and in some parts of Germany the infusion from the leaves has quite taken the place of the berry, the price of which has been an obstacle to its ready sale. Careful research work has resulted in proof that the extract obtained from the leaves has undoubted nutritive properties. In addition, a vast number of analyses have been taken which furnish data practically guaranteeing its safety as an article of diet, with an entire absence of deleterious effects. With a little boiled rice and infusion of the coffee leaf a man will support the labours of the field in rice-planting for days and weeks successively up to the knees in mud, under a burning sun or drenching rains, which he could not do by the use of simple water, or by the aid of spirituous or fermented liquors. Planters in Sumatra had opportunity of observing for twenty years the comparative use of the coffee leaf in one class of natives, and of spirituous liquors in another, the native Sumatrans using the former, and the natives of British India (imported labour) the latter. Records show, while the former expose themselves with impunity for any period to any degree of heat, cold and wet, the latter can endure neither wet nor cold for even a short period without danger to their health. Although the coffee berry can only be produced in certain climates and on soils containing marked peculiarities, the plant itself will flourish in any tropical country where the soil is sufficiently fertile, and in consequence the field for production of the leaves is almost unlimited. As a means, therefore, of providing caffeine for general consumption free from deleterious qualities, and yet containing great nutritive properties, the leaves appear to be eminently suitable," p. 5.

Under thermit process, p. 7, we read that "owing to the heat developed in these reactions and the rapidity with which they occur, an enormous temperature is produced, second only to that of the electric arc. It has been estimated at 2600°-3000°, and direct observation with a Féry radiation pyrometer has shown that the temperature of a stream of steel produced from iron oxide and aluminium, as it was poured from the crucible, was 3200° (the melting point of steel is approximately 1350°). At such temperatures the entire contents of the crucible remain liquid; the reduced metal sinks to the bottom, covered with a layer of molten alumina."

One hundred parts of thoria can hold in solid solution 6·7 parts of cerium dioxide, and as the mantle contains only about one percent of the latter, the ceria is entirely dissolved. "Although in most instances the optimum effect is attained by mixing the thorium and cerium salts in such proportions that the mixed oxides of the mantle consist of 98·8 p. c. of thoria and 1·5 p. c. of ceria, yet owing to the yellow colour of the light produced by this amount of ceria in inverted mantles, it is customary in this form of illumination to reduce the proportion of ceria to from 0·5 to 0·7 p. c.," p. 40.

"Titanox consists of titanium dioxide precipitated upon a base of finely divided *blanc fixe*. In colour it is far whiter than white lead, but not quite so white as French process zinc oxide or the best grades of lithopone. Its hiding power is twice that of white lead and is the greatest of any white pigment. Its inertness towards varnish liquids enables it to be used in compositions that can be kept without danger of livering or thickening. 100 p. c. titanox in oil dries very slowly to a soft film, and a fair quantity of a metallic drier should be used while for interior work an addition of about 30-50 p. c. of zinc oxide is advantageous, this causing it to give a firm dust-resisting film. Titanox appears to be very resistant to sunlight and to all atmospheric conditions and to hydrogen sulphide fumes," p. 72.

"Titanium oxide is used as a mordant, and in at least two cases it has an advantage over alumina; thus alizarin yellow produces with titanium as bright but a much faster colour than with alumina, whilst the scarlet obtained from alizarin orange on a titanium mordant is the fastest scarlet that can be obtained on wool," p. 73.

"The venom of scorpions (against which an antitoxin can be prepared) and spiders is probably protein in nature; of mosquitos and gnats it may be the products of certain bacteria or moulds present in the aesophageal sacs; of bees a protein-free organic base. The formic acid present in the 'venom' of ants, bees, etc., is probably not the active toxin. Many fish are also poisonous by their bites or by spines connected with special glands. Toads and salamanders have acid poisons and basic poisons in the skin glands. Jelly-fish and sea-anemones have stinging glands. Extracts of intestinal worms may be toxic," p. 176.

"With regard to liquid water, there is a great body of evidence pointing to the presence of complex molecules. It is now fairly generally held that the abnormality of water as compared with other liquids in so many physical properties is due to polymerisation. This explanation was first advanced by Whiting [A New Theory of Cohesion applied to the Thermodynamics of Liquids and Solids, Harvard University, Cambridge, Mass., 1884, p. 70], who pointed out that water at 0° may contain 25-38 p. c. and at 100° 17-28 p. c. of dissolved ice, and that the observed expansion of 4 p. c. by volume in this interval is the resultant of a normal expansion of some 8-10 p. c. by volume and a contraction due to the melting of the dissolved ice. Eight years later Röntgen [Wied. Ann., 45, 91 (1892)], independently suggested that water consists of 'ice molecules,' and water molecules the former being more complex but less dense than the latter," p. 361.

"The waxes differ from the fats in having little or no greasiness at ordinary temperatures. The greasiness of most of the fats is probably due to their containing some olein (glyceryl oleate) or some glyceryl esters of unsaturated fatty acids. There was an impression in the last century, doubtless produced by Chevreul's work on the fats, that whilst the fats contained glyceryl esters, the true waxes did not; but contained esters of higher members of the $C_nH_{2n}O_2$ series of acids with alcohol radicles other than glyceryl. As a result of this an unfortunate system was introduced of denying the name of 'wax' to those waxes that are largely composed of glycerides, and of calling them 'tallowa.' It serves no useful purpose and has the effect of upsetting the ordinary meaning both of 'wax' and of 'tallow.' By it, on the one hand, Japan wax was to be called Japan tallow and myrtle wax was to be called myrica tallow, because they are both largely composed of glyceryl palmitate; and on the other hand, sperm oil was to be described as a liquid wax, because it was thought to contain very little glyceryl esters. Refined wool fat, a soft unctuous substance, was called wool wax. The inadvisability of attempting to alter the meaning of a word in common use to suit some special scientific classification was pointed out by Gregory in Nature, 87, 538 (1911)," p. 434.

"The generally held view that the browning of wines is due to unsound grapes is not correct. The presence of stalks in the fermenting mash contributes appreciably to browning. Very acid wines are particularly prone to browning. The browning is most probably due to the oxidation of tannin-like substances of phenolic character by the action of oxidases, or by auto-oxidation, or probably by both processes. It can be prevented, at least to a considerable extent, by immediately pressing the grape mash, but this course is not always possible in practice.

"The browning of wines which is not only accompanied by a discoloration, but also with a strong turbidity and an unpleasant flavour, can be arrested by the use of sulphur dioxide in the form of potassium metabisulphite, which is added to the juice in the cask before fermentation. The yeasts can withstand without risk quantities of sulphur dioxide towards which *Bacterium gracile*, which effects the decomposition of malic acid at the close of the fermentation, is sensitive. The inhibition of the decomposition of the acid, whether it be temporary or complete, is mainly dependent on the quantity of free sulphur dioxide," p. 474.

"According to A. Dupré, fraudulent colouring matters added to red wines may be detected by dialysis, which is best accomplished by placing in the wine a cube of jelly about $\frac{1}{4}$ inch side. These cubes are made by dissolving 10 grms of gelatin in 100 c. c. of warm water, and pouring the solution into a flat dish or mould; from the plate thus obtained the cubes are cut. After 24-48 hours, the cube, on examination by transmitted light, will be found to be coloured more or less deeply by any colouring matter present, excepting the natural colouring matter, which penetrates only to a depth of $\frac{1}{8}$ inch at the most. The colouring matter of alkanet root also penetrates but slowly, whereas rosaniline, cochineal, logwood, brazil-wood, indigo, litmus, red cabbage, beet-root, *Makva sylvestris*, and *Althea officinalis* penetrate rapidly into jelly," p. 485.

Wilder D. Bancroft

The Microbiology of Cellulose, Hemicelluloses, Pectin, and Gums. By A. C. Thaysen and H. J. Bunker. 22 X 15 cm; pp. viii + 363. London and New York: Oxford University Press, 1927. Price: \$8.50. In the preface the authors say, p. v.: "In order to avoid misunderstanding it should be mentioned perhaps that the term micro-organisms has been adopted to designate all microscopic organisms whether they belong to the animal or to the vegetable kingdom, and that colloquially the word 'bacteria' has been used for all the red-shaped schizomycetes belonging to the eubacteriales. Where a distinction in the Latin nomenclature has been necessary among the bacteria, the system followed by Lehmann and Neumann and by Bergey has been adhered to and a spore-producing rod termed *Bacillus*, a non-spore-forming *Bacterium*.'"

The subject is presented under four chief headings: cellulose, hemicelluloses, pectin, and gums; the types of microorganisms associated with the decomposition of cellulose, hemicelluloses, pectin, and gums; the microbiological decomposition processes of gums, pectin, hemicelluloses, and cellulose; industrial applications.

"Pectin, which most authors regard as insoluble, is sometimes described as proto-pectin (Tschirch and von Fellenberg), and sometimes as pectinogen (Schryver and Haynes), or pectose (Carré). The proto-pectin is said to become soluble in the cell sap on the ripening of fruits, and it can be rendered soluble by prolonged boiling with water or alcohol or by treatment with dilute acids (Carré), or with salts of acids which form insoluble calcium salts, such as ammonium oxalate, ammonium tartrate, or sodium carbonate (Clayson, Norris, and Schryver). The soluble compound from ripe fruits is termed pectin by von Fellenberg and cytopectic acid by some English investigators. Von Fellenberg's pectin, which is neutral, is claimed to be the methyl ester of pectic acid. It is saponified by treatment with alkali in the cold and thereby yields methyl alcohol, amounting to some 10 per cent. of the total pectin or cytopectic acid," p. 11.

"A third line of research into the natural decomposition of cellulose and its associated substances was initiated in 1875 by Popoff, who investigated the causes of the natural evolution of methane in stagnant ponds. He found that methane is produced from cellulose

and its related substances, such as gums, deposited at the bottom of ponds, and that a methane fermentation could be artificially started if a flask filled with water and substances containing cellulose were inoculated with mud. The methane evolved during the resulting fermentation was sometimes found to be mixed with small amounts of hydrogen," p. 19

"*Bac. fossicularum*, Omelianski's hydrogen-producing cellulose decomposer, is associated with *Bac. methanigenes* wherever the latter occurs, and can therefore be obtained from mud. The rate of germination of its spores is slower than that of the spores of the methane bacillus, and this fact was utilized by Omelianski for the separation of the two. It was mentioned above that the gas evolved by the first crude culture prepared for the isolation of *Bac. methanigenes* contained hydrogen as well as methane. If such a culture is heated to 75° C. for fifteen minutes shortly after the gas evolution has commenced, the vegetative cells of the methane bacillus which have by then developed from their spores are destroyed, whereas the spores of the hydrogen bacillus, not germinated, remain unaffected by the heat. Repeating this treatment through three or four successive generations from the original crude culture, a culture is obtained which gives off a gas containing hydrogen and carbon dioxide only. It is interesting to note that when the methane organism is subjected to the same treatment it is eventually destroyed. This disposes of the possibility that the organism responsible for the evolution of the mixture of methane and hydrogen can be one and the same type, which through subjection to a high temperature loses its property of producing methane, but maintains its faculty of evolving hydrogen. That the two organisms are not the same species is also indicated by their difference in size," p. 57.

"The art of retting plant tissues for the isolation of fibres has been carried out in many countries from time immemorial, and highly developed methods for the retting of flax existed in countries such as Egypt from the earliest dynastic times. Here conditions were undoubtedly particularly favourable, the river Nile with its slow-moving and comparatively warm and soft waters forming an ideal basis for the elaboration of a natural retting process. A different method was probably adopted by the inhabitants of the Swiss lake dwellings, who, it appears from the remains found, were well acquainted with the art of retting. Here the process was probably carried out in stagnant water. Both of these methods, the retting in stagnant and in slow flowing water, were the only two anaerobic retting processes in use up to the middle of the nineteenth century. They are still extensively used, the former in Ireland and Italy, the latter in Holland, Belgium, and Germany," p. 163.

"The ochre pigment formed by many cellulose-decomposing bacteria was examined by Hutchinson and Clayton in their investigations on *Spirochaeta cytophaga*. They found that the pigment is soluble in the ordinary fat solvents, yielding a canary-coloured solution with ether, an ochre-coloured solution with petroleum ether or chloroform, and an orange-coloured solution with carbon bisulphide. On evaporation of these solutions an oily orange-coloured residue remained. The pigment gives color reactions resembling those of carotin. It therefore resembles the lipochrome pigments found in many bacteria, for instance in *Staphylococcus pyogenes aureus*," p. 189.

"Both in the manure heap and in the compost heap the microbiological changes, resulting in the 'ripening' of the heap, aim at the conversion of the vegetable tissues present into compounds which will assist in maintaining and increasing the fertility of the soil. Primarily the heap is converted into the so-called *beurre noir* of the early French investigators, now generally described under the name humic substances. To carry out these changes in the soil itself has long been known to be deleterious to plant life unless sufficient time is allowed to elapse for a fresh state of biological equilibrium to be established. This harmful effect was demonstrated by Fred in the case of green manure. Where seed was sown immediately after ploughing in green plants as a manure, the seeds, or the seedlings germinating from them, were destroyed by fungi, and possibly bacteria, active in the conversion of the green manure. The micro-organisms thus attacked both the tissues which they were intended to destroy, and the other forms of vegetation present within the sphere of their activity. Not until the equilibrium of the soil-flora has been restored, on the complete

destruction of the green manure, can plant life benefit from the resulting decomposition products. In the case of green manure this destruction is usually completed in a few weeks," p. 195.

"The problem of the decomposition of cellulose and hemicellulose under water is at least equal in importance to that of their destruction in the soil. In lakes, marshland, and canals, in tropical climates, in mangrove swamps, and in the sea of all climates, tremendous quantities of vegetable debris composed largely of cellulose or hemicelluloses accumulate and decay, chiefly through microbiological activity. Very little is known of the reactions involved except that marsh gas is frequently formed as a result of the decay. This gas at first remains entangled in the mud of the water bed, but eventually rises to the surface of the water, either as bubbles or sometimes in a continuous stream. It is this gas which, when becoming spontaneously ignited, was known of old as the will-o'-the-wisp," p. 213.

"When hay or other plant material is loosely stacked before it becomes dry, it shows a tendency to heat or sweat, a phenomenon which in extreme cases may result in its spontaneous ignition. As in the case of ensilaging, the reactions involved have been ascribed to microbiological, plant physiological, and chemical agencies; but, in spite of statements to the contrary, available evidence undoubtedly favours the explanation that micro-organisms are responsible for most of the earlier stages of the reactions. Miehe, who undertook a comprehensive study of the phenomenon, came to this conclusion, and Haldane and McGill in a later publication confirm this view after due consideration of the evidence brought forward by Boekhout and de Vries in favour of a chemical explanation, and of Tschirch's suggestions, attributing the heating to the activity of oxydases and reductases secreted by the plant tissues," p. 201.

"Just as the tobacco fermentation shows analogies to the spontaneous combustion of hay, so do the cacao fermentation and perhaps the coffee fermentation resemble the silage fermentation and much light could undoubtedly be thrown on both of these processes if they were considered from that point of view," p. 237.

"Assuming that the decay in the peat bog does proceed under waterlogged and more or less anaerobic conditions, there is every justification for asserting that, in the best of cases, microbiological activity must cease in the peat before the cellulose and the hemicelluloses of the submerged plant material have been approximately eliminated. The complete disintegration of the plant material and the progressive elimination of the cellulose, which Fischer and Schrader have undoubtedly shown to occur, must therefore be performed by other agencies than micro-organisms, which it would be beyond the scope of this volume to discuss.

"Some evidence for this conception of the formation of peat and coal has been brought forward in a recent paper by Thaysen, Bakes, and Bunker. It is suggested in this publication that microbiological activity ceases in the upper layers of the peat bog before the bulk of the cellulose has disappeared, and that the subsequent destruction of the cellulose proceeds on lines similar to those active in the production of carbohydrate humus from linen cloth through ageing. It is shown that the humus compounds of a normal peat bog, after chlorination by the methods recommended by Eller and his collaborators, can be split up into two substances, one identical with the humus compound obtainable from quinones and lignin, and the other with the composition of the artificial humus compound obtainable from sugars and other carbohydrates by the action of acids. The latter type of humus was also obtained by these workers from samples of Egyptian mummy cloth made of pure undyed linen which had decayed in the absence of micro-organisms," p. 248.

"Fungi decaying the heartwood of living trees are not commonly found in wood used for aeroplane structures. Where they do occur, they are effective proof that the wood used was originally infected, and that sufficient care had not been exercised in eradicating the seat of infection. Decay in wooden aeroplane parts has become far more important in recent years, since large numbers of spare parts have often to be stored for a long time. Such parts should, in Boyce's opinion, be kept under conditions which will permit of good ventilation and will ensure that the moisture content of the wood does not exceed 11 per cent.

Aeroplanes in use, quite apart from those employed in very damp tropical climates, are in parts exposed to decay, particularly near the engine and around the base of the wings, where an increased humidity and a somewhat higher temperature prevail," p. 296.

"Though the marsh gas which escapes from the ground in some localities has been used as a combustible gas for domestic purposes for many years, and though numerous investigations have shown that the microbiological decay of vegetable debris frequently gives rise to the evolution of such gases, especially methane and hydrogen, few attempts have so far been made to utilize these reactions for the commercial production of gaseous fuels. Those made have not yet succeeded in establishing this industry, even in localities where vegetable debris is abundant and coal deficient. This no doubt, is largely due to the existing imperfect knowledge of the microbiology of hemicelluloses and cellulose, and to the consequent difficulties encountered in attempting to control the breakdown of these substances on a technical scale. There is no *prima facie* reason to believe that such processes should necessarily be uneconomical. On the contrary, they appear to constitute a fruitful field for future investigations," p. 313.

Wilder D. Bancroft

The Chemistry of Wood. By L. F. Hawley and Louis E. Wise. 23 X 17 cm; pp. 334. New York: Chemical Catalog Company, 1926. Price: \$6.00. In the introduction, p. 15, the authors say: "To the best of our knowledge, no attempt has hitherto been made to bring together within the compass of a single book, data pertaining solely to the chemistry of wood. Our own attempt to develop a monograph on this subject therefore resembles a pioneering adventure. We have worked unhampered by trials or precedents, and if our volume contains (as it may) numerous errors of commission and omission, we feel that at least it serves to summarize the outstanding contribution on a subject that has received but scant attention in the United States.

"The results of purely scientific investigations on wood chemistry have been stressed and we have attempted to point out the many gaps and loopholes in our present knowledge. This has led us occasionally to indicate what new avenues of investigation might profitably be opened in the future. In the case of moot questions, we have attempted to present the experimental data and to discuss the viewpoints of the various investigators open-mindedly. On the other hand, we have consistently attempted to differentiate between *speculation* and *investigation*."

Under "Chemical Components of Wood" the chapters are entitled: cellulose, the principal constituent of the cell wall; polysaccharides of wood; lignin; lignin derivatives and the constitution of lignin; extraneous components of wood. Under the general heading of "Proximate and Summative Analysis of Wood," we find the chapters: introduction; the sampling of wood—miscellaneous determinations; the determination of cellulose; the determination of pentosans and hexosans in wood; the determination of lignin; analytical data and their significance. Under "Decomposition of Wood" we have the chapters: combustion of wood; the decomposition of wood by heat; hydrolysis of wood; delignification of wood; decomposition by concentrated alkali. The last section deals with "Wood as an Industrial Material" and has only the two sub-heads: physical properties; the deterioration of wood.

"Different hypotheses regarding the size of the cellulose molecule have also appeared in the cellulose literature. Views on this subject may be briefly summarized as follows: (a) a relatively enormous molecule made up of a great number of anhydrodextrose residues, many of which go to make up the anhydrocellobiose linkages referred to above: (b) a large aggregate made up of comparatively small units, each one of which contains the anhydroglucose linkage a relatively small number of times. The units are held together in the larger aggregate by means of secondary valence or in some similar way which is not yet fully determined. From the work of Herzog and his co-workers it appears that the cellulose aggregate is crystalline.

"The viewpoint outlined under (a) although held by individual investigators, has been largely displaced by that referred to under (b)," p. 25.

"Perhaps the most modern and generally accepted concept of lignification has been formulated by Wislicenus. Realizing that lignin could not be considered a definite compound, and that the analytical data on lignin varied with nearly every investigator, Wislicenus undertook a dynamic study of lignin formation. He determined the content of adsorbable (colloidal) matter in the cambial saps of a number of trees by treating a given volume of sap with some substance like alumina, and determining the amount of adsorption by comparing the residue obtained by evaporating the treated sap to dryness, and subtracting this residue from that obtained by evaporating an equal volume of untreated sap. These data led him to believe that the period of maximum colloid content of the sap coincided with the period of most rapid and intensive growth. As a result he enunciated the sweeping hypothesis that lignin is composed of the sum total of colloiddally dissolved hydrosols (of high molecular weight) which are deposited by adsorption from the formative (Bildungs) or cambial sap upon the surface of the cellulose fiber, the synthesis of which precedes lignification. While the assumption is made that adsorption is primarily responsible for lignification, the possibility of chemical interaction between certain components of the heterogeneous lignin and the cellulose gel is not excluded. Wislicenus was careful to make his hypothesis broad enough to include both the older encrustation theory by Payen, and the chemical compound theories of Hoppe-Seyler, Lange and Grafe," p. 48.

"The cause of the colorations has been attributed to various components of the wood. Since the colorations disappear after the wood has been treated with NaHSO_3 or with hydroxylamine, the reactions have often been associated with aromatic aldehydes. Czapek was able to remove from wood a very small amount of substance, apparently an aldehyde, which still gave all the color reactions of the original wood. This substance, which was removed by heating wood with ZnCl_2 and extracting this solution with C_6H_6 or ether, he termed *hadromal* but he was never able to isolate it in sufficient amount to permit its complete identification. This *hadromal* could not have represented more than a small fraction of that part of wood which is ordinarily termed lignin, and Czapek's work clearly showed (what a number of other investigators had suspected) that the brilliant lignin color reactions were really due to a minor constituent of the wood. This was confirmed by Crocker who showed that both oil of cloves and oil of sassafras gave colorations with phloroglucinol and with aniline. The absorption spectra of these colored substances were identical with those of the corresponding substances obtained by the interaction of the same reagents with wood. In other words, the substance in wood that is responsible for the coloration is also present in small amount in certain essential oils. Crocker's results show that the color tests do not characterize any appreciable part of the lignin. They are apparently indicators of a small amount of an aldehyde (coniferyl aldehyde?) which normally accompanies the lignin fraction," p. 50.

"In demonstrating some of the striking analogies between the behavior of coniferyl alcohol and lignin of spruce wood, Klason pointed to the fact that both of these substances give similar *aromatic* compounds when fused with alkali. This finding has lent support to the fairly general belief that an aromatic nucleus is preformed in lignin, since it has been shown repeatedly that the fusion with alkali of various lignin fractions and lignin derivatives gives rise to protocatechuic acid and pyrocatechol, besides the so-called indefinite "lignic" acids and oxalic acid. A thorough investigation of this fusion was made by Heuser and Winsvold and later by Heuser and Hermann. The former also give an excellent résumé of the literature. Heuser and Hermann showed that when the KOH fusion of a lignin fraction (isolated from spruce by means of hydrochloric acid) was carried out (in nickel dishes) in air, at $240^\circ\text{--}250^\circ$, the products were largely the "lignic acids," and oxalic acid, while the yields of crude protocatechuic acid and pyrocatechol were 16.4 and 3.7 per cent respectively. They also showed that the pyrocatechol was a secondary product formed from the protocatechuic acid, and that when the fusion was carried out in hydrogen (in place of air), the oxalic acid yields dropped considerably (sometimes to the vanishing point). When an iron crucible replaced the nickel crucible in the fusion, and an atmosphere of hydrogen was used, no oxalic acid was obtained but the pyrocatechol yield rose to 21 per cent, and about 10 per cent of the crude protocatechuic acid was formed. If, however, the fusion was

carried out in iron, an atmosphere of hydrogen, and in the presence of ammonium carbonate, 23 per cent of crude protocatechuic acid, and only 7 per cent of pyrocatechol were formed, with no change in the "lignic acid" yield and without production of oxalic acid. They showed definitely that the fusion of cellulose with KOH yielded neither protocatechuic nor pyrocatechol, irrespective of whether they used iron or nickel crucibles or carried out the fusion in air or hydrogen. In nearly all cases they obtained about 90 per cent oxalic acid, besides appreciable amounts of acetic acid and small amounts of formic acid. Evidently the oxalic acid formation from cellulose was not due to oxidation. Later Heuser and Roth showed that xylan on alkaline fusion yielded only traces of aromatic compounds and that these could be attributed to the presence of impurities in the material used," p. 58.

"While the coloring principles and dyes in plants are usually associated with the leaf and flower, and are largely absent from fruits, roots, bark, and wood, there are cases in which the woody tissue is unusually rich in these substances. Classical examples are the brazilwoods and logwood; and other examples, such as the wood of "old fustic," osage orange, and young fustic, might be cited. Some of the dyestuffs thus obtained from wood are still commercially valuable, although the importance of others has receded with the growth of the synthetic dye industries.

"In many cases the dye itself is not preformed in the wood, and its precursor (i.e., the coloring principle) may be extracted from the finely divided wood by means of ether, alcohol, or water, or by a succession of solvents. The coloring principles are therefore not a part of the cell wall but must be grouped with the extraneous substances of wood.

"The most important commercial dyestuff is obtained from logwood (*Campeche wood*, *Haematoxylon campechianum* L.). a tree which is indigenous to South America and the West Indies and which belongs to the *Cesalpinae* group of *Leguminosae*. . . . Logwood is widely used in producing "blacks" on wool, silk, and (to a lesser extent) on cotton. It is one of the few natural dyestuffs that has withstood the competition of the synthetic dyes," p. 100.

"The East Indian satinwood (*Chloroxylon Swietenia*) contains a crystalline substance, chloroxylonine, $C_{22}H_{25}NO_7$, m. 182-3°, which appears to be responsible for the dermatitis caused by the action of the sawdust of this wood. The Central American *cocobolo* wood (*Dalbergia spp.*) used in the manufacture of knife handles in the U. S., also exhibits toxic properties that may be due to the presence of an alkaloid, the nature of which remains undetermined. Another alkaloid, also unidentified, is a component of the wood of an inferior type of Knysna boxwood of Kamassi wood grown in Southeast Africa. This substance is a heart depressant and resembles the curare-arrow poison in its action.

"Occupational diseases due to the poisoning caused by these and other woods depend on the sensitiveness of certain individuals to the toxic substances in the wood. The suggestion has been made that only laborers immune to such poisons be selected for work in the industries utilizing cocobolo, satinwood, etc," p. 118.

"As we will see in the next chapter, wood begins to decompose at about 275°C. and that decomposition is exothermic in character. During the course of this decomposition combustible and incombustible gases and vapors are formed, and a combustible residue, is left behind. Since there is no considerable decomposition of wood below this temperature, it would not be expected that the wood could ignite sooner because the oxygen of the air certainly could not combine directly with the solid wood substance at such low temperatures. The ignition temperature of all woods would be expected to be at about 275°C. under the optimum conditions. This theory probably holds except (1) as the physical properties of the wood, such as porosity, influence the surface of contact between the wood and air and (2) for the presence of extractives with low ignition temperatures, such as volatile oils. If the ignition takes place at about 275°C. it means that the vapors or gases formed by the decomposition of wood by heat normally ignite at this temperature or that they ignite at a lower temperature than usual due to the catalytic action of the residue of charcoal, or else it means that the exothermic heat carries the temperature locally above 275°C. and starts the combustion. The ignition temperature cannot be much above 275°C.

because if so it would be possible to distil wood to a residue of charcoal in the open air without combustion which seems impossible when the ready ignition of freshly formed charcoal is considered," p. 187.

"The combustion of wood may be considered to take place in two stages: 1st, the combustion of gases and vapors given off by the exothermic decomposition of wood and 2nd, the combustion of the solid residue of charcoal left behind after the exothermic reaction is finished. These stages may not be sharply defined, since volatile combustible material is driven off from the original charcoal if it is further heated after the completion of the exothermic reaction but there is certainly a change in the character of the combustion at about this time. This is further indicated by the fact that about half the vapors and gases given off during the exothermic reaction are incombustible (CO_2 and H_2O), while nearly all the gases given off afterwards are combustible. It can readily be conceived therefore that the outside of a large stick of wood may be heated to the ignition temperature and burn through the first stage of combustion without heating the interior of the stick above 275°C . On account of the low conductivity of charcoal, the heat from the combustion of the charcoal on the outside of the stick may not be conducted inward rapidly enough to heat more wood to the distilling point and the "fire may go out." This accounts for the difficulty in burning large chunks of wood, such as stumps or logs, unless the conditions are such as to keep the heat from being radiated away. A large pile of stumps may be burned without much difficulty but the burning of a single stump is a hard job. One piece of wood keeps another afire.

"This property of burning rapidly on the outside, charring a thin layer, and then being extinguished entirely or burning very slowly is a valuable one for wood used for construction work exposed to fire hazards. In fact steel under the same conditions and carrying the same load may be rapidly heated through and not infrequently may lose its strength and drop its load sooner than the wooden member," p. 188.

"At one time the ashes obtained by the combustion of wood were of considerable importance as a source of potash; in fact it is hardly a century ago that in newly settled localities in this country the chief value of wood lay in its potash content. The pioneers in clearing their land piled the logs until they were dry enough to burn and after burning carefully collected the ashes. This was frequently the first valuable product from the land and the only one with a cash value. For many years after this period wood ashes were sufficiently valuable to pay for their collection and use as fertilizer or as a source of crude potash. Perhaps even today some home-made soft soaps require the saving and leaching of ashes from the farmer's stove.

"Since the commercial production of potassium salts from the Stassfurt deposits, the value of wood ashes has diminished and they are no longer an article of commerce. In most places where large amounts of wood are burned as in sawmill power plants or in waste burners, the draft through the fire-box is so rapid that the ashes go out with the smoke. Where wood is used in small amounts as for domestic fuel the cost of collection of the ashes is prohibitive," p. 193.

"There is no apparent relation between the physical properties and chemical composition of pulps. It is known that certain cooking conditions produce pulps with certain desirable properties and in general the well-cooked pulps rather than the under-cooked possess the better properties, but the corresponding differences in chemical composition are unknown. The more complete cooking may, of course, leave a smaller residue of lignin in the pulp but it is not likely that the presence of more or less lignin within low limits has any direct bearing on strength. The weakness of certain over-cooked or burned pulps is probably due to slight and obscure chemical changes such as those that take place in drying or steaming wood at temperatures just above 100°C ," p. 254.

"The exact requirements of the cellulose to be used in making cellulose esters are not known. There are specifications for the cotton cellulose used for this purpose but perhaps wood pulps might be satisfactory which did not comply with these specifications. Since a different set of impurities are to be guarded against in the case of wood pulps, a different set of tests should be prepared. It is known that sulfite pulps from spruce are being used

in making viscose and it has been reported that wood pulps have been successfully used for nitration but the detailed effects of variations in composition on the properties of the esters have never been published. If small pentose and mannose yielding residue are not harmful and if either a little color or a slightly higher alkali solubility can be allowed, then wood pulps can be readily prepared for use in making cellulose esters," p. 262

"The ease with which liquids can be forced into wood is of interest chiefly in connection with preservative treatments or with chemical reactions like the pulping processes where it is desired to bring the reagent into contact with all parts of the chip. Most of the available data were obtained in experiments in treating wood with coal-tar creosote. There is very little correlation possible between penetrability and structure and there are several conflicting theories as to just how creosote or other liquids pass into and through wood under pressure. We will, therefore, state the generally accepted facts in regard to treatment with creosote and leave the details of experiments and theory to the special literature on the subject.

"The penetration of creosote into wood under pressure is very much greater in the longitudinal direction than in either of the other directions and there is commonly little difference between radial and tangential penetration. Sapwood is commonly easier to treat than heartwood. Summerwood is commonly easier to treat than springwood, especially in softwoods. Dry or partly dry woods are easier to treat than green woods. There is a wide variation in the ease of penetration of different species.

"There is one satisfactory relation between structure and penetration. Red oaks, for instance, are very easily penetrated in the longitudinal direction through the pores, while white oaks with very similar structure are very difficult to penetrate. This difference is due to the fact that the pores of white oak are obstructed by peculiar, thin-walled, irregular, growths called tyloses. In wood with pores not obstructed by tyloses the longitudinal penetration takes place through the pores but in hardwoods with obstructed pores, the path of the liquid is a subject of controversy. The debate hinges on whether or not the membranes of the bordered pits are perforated, permitting liquids to pass from one tracheid to another.

"Obviously, there is a great need for further information on the mechanism of the passage of liquids through wood. Much of this information may be obtained by purely structural, microscopic studies, but further information is also required on the transfusion of liquids absorbed in the cell wall which may be called a physical or physicochemical study," p. 280.

The authors are apparently not aware, p. 302, that in some cases of blue wood the color is a structural and not a pigment blue.

Wilder D. Bancroft

Physikalisch-chemische Metamorphose. By Ernst Cohen. 23 × 16 cm, pp. 135. Leipzig: Akademische Verlagsgesellschaft, 1927. Professor Cohen was the first non-resident lecturer at Cornell under the gift from Mr. George F. Baker. These lectures were first published in English (31, 1593) and now appear in German, reversing the usual order.

Wilder D. Bancroft.

A Text-Book of Inorganic Chemistry. By Fritz Ephraim. Translated by P. C. L. Thorne. 24 × 17 cm; pp. 807. London: Gurney and Jackson, 1926. Price: 28 shillings. The German edition was reviewed in 1924 (28, 302). We welcome an English edition because it is at present very difficult for students to get a reading knowledge of German at school. This translation is based on the third German edition.

Wilder D. Bancroft.

FIRST REPORT OF THE COMMITTEE ON PHOTOCHEMISTRY, DIVISION OF CHEMISTRY AND CHEMICAL TECHNOLOGY, NATIONAL RESEARCH COUNCIL

BY H. S. TAYLOR

The following six papers represent the initial effort of the Committee on Photochemistry¹ of the Division of Chemistry and Chemical Technology of the National Research Council to promote further interest in the problems of photochemistry. During the last two decades the subject has undergone a considerable expansion consequent upon the adoption of newer ideas in the realm of physics with respect to the nature of light, and the processes of its absorption by atoms and molecules. The concept of quanta of light and of quantised absorption by atomic and molecular species has led to an entirely different attitude towards photochemical problems from that which was held in the first decade of the present century. The acceptance of the quantum theory has been more complete upon the part of physicists than by chemists and among the latter there still remains a degree of conservatism with respect to the older concepts.

The attempt has been made in the articles which follow to discuss some of the problems of photochemistry from both standpoints. In the article by Professor Bancroft will be found an exposition of what might be termed the classical attitude to photochemical work. On the other hand the modern physical point of view with respect to the absorption process and the changes produced in the absorbing system by the energy absorbed has been stated in its pertinent aspects by Professor L. A. Turner of the Physics Department of Princeton University. The quantum concept, in its relation to the chemical reactions occurring, has formed the subject of Professor Taylor's contribution. Since all quantitative photochemical work must eventually involve the measurement of light absorption and the quantitative evaluation of light energy incident to the photo-system, this problem has been very comprehensively treated by Professor G. S. Forbes and by Dr. H. de Laszlo. The subject of photochemistry has much in common with the production of chemical reactions by alpha-particles and by other sources of ionisation. This forms the subject of a final article by Professor S. C. Lind.

The whole group of contributions is offered in the hope that progress in photochemical research in the United States may be stimulated by their perusal. It is planned to follow this report by others which deal more extensively with particular problems in the field.

¹ The Committee is composed of the following members: Professors W. D. Bancroft, G. S. Forbes, S. C. Lind, F. Daniels and H. S. Taylor, *Chairman*. The articles which follow have not been submitted to the Committee as a whole. The individual authors are alone responsible for their respective contributions.

EXPERIMENTAL TECHNIQUE FOR QUANTITATIVE STUDY OF PHOTOCHEMICAL REACTIONS*

BY GEORGE SHANNON FORBES

Introductory. Experimental photochemistry is such a many-sided subject that the scope of this paper must be severely restricted. It deals with chemical reactions evoked by light from external sources, and from the red to the beginning of the Schumann region. Heterogeneous systems are not discussed.

Photochemical literature is burdened with an unduly large proportion of articles which are useless or misleading because part only, if any, of the essential variables were measured. Photochemical generalization, for insufficiency of sound experimental data, is still uncertain regarding many vital matters. Only consistently quantitative methods can banish the dubious hypotheses which the pseudo-quantitative type of paper engenders.

In what follows, therefore, the emphasis is placed upon monochromatic procedures, in which both energy absorbed and substance transformed are adequately measured. It will be evident that a considerable degree of accuracy is compatible with reasonable simplicity and economy. The treatment is in no sense historical or encyclopaedic, but rather selective and critical; the same is true of the bibliography, which includes less than a third of the papers which received more than passing consideration.

Sources of Information. Most details are given by reference; also whole topics when connected and satisfactory expositions are accessible. A dagger indicates a reference list of importance. Grateful acknowledgment is made of assistance rendered by Mr. R. M. Fuoss in connection with the library work.

It will be recalled that the Research Information Service of the National Research Council, Washington, D. C., "places at the immediate command of individuals, institutions and firms, information concerning scientific instruments, apparatus, lantern slides, laboratory construction and equipment, bibliographies and reference lists both published and unpublished, research problems, projects, methods, funds, personnel and other subjects of interest to investigators." It will also give the names of dealers, domestic and foreign, which can supply specified instruments and apparatus. Many dealers, in turn, are glad to send reprints, folders or booklets on the theory and use of photochemical instruments.

* Contribution from the Chemical Laboratory of Harvard University.

Light Sources. (General). The ideal photochemical light source is extremely intense and concentrated, and should be efficient, convenient and economical. Much of its total energy is radiated through a relatively small number of lines ²⁶ evenly spaced in the actinic region. The continuous background should be relatively weak. It should be shaped like a monochromator slit, and better still have the same dimensions. Rapid variations in intensity about a constant mean value can usually be tolerated, and evenly progressive changes invite interpolation, but violent fluctuations are incompatible with quantitative work. A concave mirror behind the source²⁷ or a projection apparatus²⁸ increases the intensity of illumination. Mirrors can reflect radiation upon the sides of the vessel²⁹ and a mirror placed behind the vessel multiplies absorption by a factor between 1 and 2^{124, p 284}. A weak or unsuitable source takes such heavy toll in time spent and in quality of results, that economy is the worst form of extravagance. The permissible minimum of light intensity is discussed below under "Analytical Methods."

Sources with approximately Continuous Spectra

Sunlight^{16, pp. 15-34} costs nothing, and is extremely intense in the visible, especially at high altitudes^{16, pp. 17-22} or in the tropics^{30, 31}. Its spectrum, which practically terminates at $300m\mu$ ^{16, p. 24} is for photochemical purposes best imitated by the blue gas-filled tungsten lamp,^{16, p. 117} or by the snow-white flame arc.³² Combinations of the mercury vapor lamp with various thermal radiators are its equivalent for color-matching only.³³ The mercury vapor lamp with a crown-glass filter is said to behave like sunlight in fading tests.³⁴ Lenses or concave mirrors concentrate sunlight further, and water filters^{16, p. 49} mitigate the thermal effect. The extreme variability of sunlight,³⁵ the need of a heliostat^{18, pp. 114-117}, and the fact that its spectrum is continuous, except for the dark lines, all handicap quantitative monochromatic work. Such drawbacks, however, must not discourage further investigation of its immense possibilities.

Solid Radiators^{16, pp. 107-164}. Incandescent filaments, straight or coiled, should, if used with a monochromator, approximate the dimensions of the slit. The thin glass bulb transmits much ultraviolet, and a quartz window³⁶ can be added. Overloading greatly increases the ultraviolet output,³⁶ though shortening the life of the lamp. The Nernst glower³⁷ is still made by the Glasco-Lampen Gesellschaft, Berlin; a laboratory recipe has been published;³⁸ its spectrum is very faint beyond $250m\mu$ ^{16, p. 109}. "Glowbar" is useful for infrared work only. If magnesium^{24, p. 102} could be fed uniformly into oxygen over a considerable period, it would be of greater value.

Flames of burning gases are infrequently used in photochemical work. Considerable ultraviolet is emitted by acetylene properly burned in oxygen^{24, p. 101} and by the carbon disulfide-oxygen lamp^{39, 40}.

High Tension Discharges under Water^{15, pp. 24-6} between electrodes of aluminum, brass, tungsten, etc., from a step-up transformer coupled or not with a Tesla coil produce spectra continuous to $210m\mu$. Such sources are more valuable for photographic work^{41, 42} on absorption spectra than for photochemical reactions.

Sources with Discontinuous Spectra

Arcs¹⁵, pp. 27-29; 16, pp. 107-164, excepting flaming arcs, are not well shaped for use with slits. Feeding mechanisms allow considerable fluctuations. The ordinary carbon arc's spectrum is weak beyond $250\text{m}\mu$ ¹⁶, p. 107. The spectral energy distributions in crater and flame are unlike, and the lines are disadvantageously spaced. Bassett⁴³ has studied carbon arcs carrying several hundred amperes. Carbon electrodes can be cored or impregnated¹⁶, p. 124. The flaming arc has been carefully studied, especially by Mott⁴⁴, 45. Of many metals, copper, cadmium, iron and tungsten are most frequently employed as electrodes. King⁴⁶, 47 has operated arcs between metallic rods with 1000-2000 amperes, producing normal and enhanced spectra in great intensity. The copper arc of Meyer and Wood⁴⁸ gives radiations of very short wavelength. W. Taylor^{48a} found the "Pointolite" lamp very intense in the visible.

Sparks between metallic electrodes are almost indispensable for work below $250\text{m}\mu$. Warburg's zinc sparks^{10a}, p. 135 gave at $254\text{m}\mu$ a thousand-fold the intensity of his mercury vapor lamp. The elements of the second and third groups give advantageous spacing of lines.²⁶ Many papers on the subject have accumulated⁴⁹, 16 pp. 140-144 but more data on absolute spectral intensities under specified conditions would be welcomed by photochemists. Warburg¹, 2, 6, 10, Lenard and Ramsauer¹¹, p. 1521, also others⁵⁰, 163, 203 have described adequate installations. Many such outfits¹⁵, pp. 22-4 are underpowered. A transformer consuming several K.W. and yielding at least 20,000 volts should be used. Special wiring may have to be run through the building. Mica condensers are better than Leyden jars. Warburg¹ housed his spark gap in a chamber with a quartz window and an air-blast. He threw its image on a screen, and kept it constant by a feed worked by a glass rod,² but intensity varied 3-6%.⁶ Harrison and Hesthal⁵¹ combatted unsteadiness by rotating the lower electrode, and by regulating the gap and the primary impedance. Kowalski^{51a} by adjusting the capacity, brought the greatest intensities into the middle ultraviolet.

Mercury Vapor Lamps of fused quartz approximate the ideal light source in so many respects that most photochemists use them. Numerous modifications are described¹⁵, pp. 30-50. The cathode is always of mercury, the anode of mercury or of tungsten. In the latter case reversal of polarity must be avoided. The commercial lamps have sealed-in electrodes, and not all of them

can be operated in both a horizontal and a vertical position. For alternating currents a rectifier is ordinarily used instead of a three-electrode lamp, but a two-electrode lamp for high frequency has been described.⁵² The manufacturers supply detailed directions for operation. A lamp with sealed-in electrodes is slow to attain a steady state. Light intensity varied with line voltage and ventilation. They will not stand heavy overloading. First cost is high, and freshening, when the ultraviolet transmission has deteriorated^{53, 54, 120A, p. 546}, is expensive in time and money.

The unsealed constant-pressure lamps recently described avoid the above difficulties^{55, 56, 57, 58}. The disadvantages of heavy overloads are relatively small. Dr. P. A. Leighton of this laboratory has constructed an open lamp water-cooled and with adjustable pressures which can maintain for hours galvanometer deflections constant within a fraction of a percent. When extreme concentration of light is not required, the bore of the constricted arc should be four rather than two millimeters.⁵⁹ The ends of the luminous column should not be opposite the slit. The constriction can be bent to match a collimating slit curved to neutralize distortion of the beam at the exit slit. The constriction can be omitted and the lamp immersed in a tank so that the water level stands about a centimeter below the slit. The capillaries used to restrain oscillations⁵⁶ can be made quite large if blocked with steel wires. A powerful air-blast can replace water cooling.⁵⁹ Fuses afford protection against short circuits caused by collapse of the luminous column.

The recently invented mercury vapor induction lamp devised by Foulke⁶⁰ has great possibilities for photochemistry. It has no electrodes, but the vapor is excited by a rapidly changing electromagnetic field. Intensity is greatly increased by small amounts of inert gas, as is the case with lamps having electrodes.⁵² A lamp of 10 cm. radius run on 2.5 K.W. gave a horizontal candle power of 20,000. Unfortunately the cost of installation is considerable.

Vapor Lamps with Other Metals^{15, pp. 66-8}. Stark and Küch⁶¹ tried out melted cadmium, zinc, lead, bismuth, antimony, tellurium, selenium. Lowry and Abrams⁶² used solid cadmium. To avoid breakage Sand⁶³ added zirconia, and Bates⁶⁴ gallium. Sodium-potassium alloy has been used.⁶⁵ Amalgams contain such ingredients^{13, p. 14; 16, p. 150; 66} as cadmium, zinc, thallium and caesium to enrich the spectrum; the added metal collects at one pole or on the walls, and inconstancy results.⁶⁷ The Bates lamp would seem to be the most intense, steady, and practical of this group. Dr. George K. Burgess of the Bureau of Standards, in a private letter to me stated that all the cadmium lines including those in the region 250 m μ to 185 m μ can probably be obtained with greater intensity from this lamp than from any other source.

Precautions. Although the dangers of ultraviolet light have been minimized,⁶⁸ all will agree that high-grade welding goggles^{69, 70, 15 pp. 72-76} with sides must be worn near a powerful source. It will pay to buy a light and a dark pair. Avoiding lateral exposure, ordinary spectacles afford some protection. Welding masks, gauntlets, and aprons follow goggles as exposure becomes more severe. Ellis and Wells discuss^{15, p. 209} susceptibility, with emphasis upon diabetes. A ventilated lamp-house with heavy red glass windows protects the experimenter and keeps ozone out of the room. Rubber is shellacked or wound with electric tape. A paint of zinc oxide and lampblack absorbs stray radiations.⁷¹

Spatial Energy Distribution. If the distance exceeds ten-fold the greatest dimension of source or reaction vessel, the inverse square law holds within one percent^{20, p. 422}. Deviations for other conditions have been worked out²⁰. "Distance" is neither to the front face nor to the centre of the mixture^{15, p. 65} but rather to that imaginary surface at which half the total absorption has occurred. Unsymmetrical distribution, as with carbon arcs or incandescent filaments, can be mapped^{20, pp. 429-433; 23, pp. 123-129}. Integrals for various dimensions of source and cell are given^{17, pp. 435-9}. Tr  mpler⁷³ gives a formula for mercury vapor lamps at short distances. The conduction of heat away from the ends of such lamps makes the energy E_a radiated perpendicular to their axis, at the ten-fold distance d , nearly equal to $E/4\pi d^2$ per square centimeter of receiving surface, where E is total energy consumed by the lamp.

The Reciprocity Law predicts that, with other variables constant, total photochemical effect is proportional to the product of intensity and time. Unless the fraction decomposed is small, it is better to find whether the effect is constant for constant products of intensity and time. The limitations of the "law" have been systematically studied⁷² for the photographic plate only. Allmand⁷¹, p. 342 gives a non-critical summary of verifications and violations⁷⁷ reported, 1914-25. He also discusses threshold intensities. Wood,⁸⁰ also Pringsheim⁸¹ report that enormous intensities evoke reactions non-existent with moderate ones. If the "law" does not hold in a given case, light intensity must be defined in stating quantum yields. Also the usual mathematical treatment of the illuminated system would have to be corrected for variation in photochemical efficiency with varying depth in the reaction layer. The need for consideration of dark reactions, induction periods and after effects in studies of the reciprocity law is obvious.

Quantitative Measurement of Radiation Intensity¹², pp. 731-4.

Intensimeters⁸² with Sensitivity Curves.⁸³ Photo-electric cells are now made in America which are practically free from time-lag,⁸⁸ fatigue and deterioration, and with intensity-current curves that are almost linear. These are points of great superiority over older types.⁸⁴ Photo-electric cells are highly selective, but different alkali metals or hydrides have sensitivity peaks at different wave-lengths.⁸⁵ They are most useful as null instruments^{86, 87} in comparing two intensities at the same wave-length.

Fluorometers^{89, 90} are simple and inexpensive though not very precise. Sensitivity curves, and relations between incident and emitted light are given by Winther.⁸⁹

Photographic plates have been studied by Harrison^{51, 91}, who mapped their "characteristic surfaces" generalizing the three coordinates intensity, time and density for each of a number of wave-lengths. The ultraviolet range is increased by bathing with fluorescent oils.⁹² Such data make it possible, by a simple photographic photometer,⁹³ to measure the spectral energy distribution of false light (see below), and to measure absorptions (see Dr. de Laszlo's report).

Chemical Actinometers should employ only photochemical reactions which are reproducible, which involve only one phase, and whose photochemical efficiency is known for each of a number of wave-lengths. When speed of reaction falls off with decreasing concentrations, fresh reactants must be substituted. Silver halide paper actinometers are extremely crude devices. The Bunsen¹⁴, p. 373 is not reproducible, the Eder¹⁴, p. 461 forms a precipitate. The uranyl oxalate photolysis,⁹⁴ in spite of complications, has many advantages. It is unfortunate that none of the reactions so carefully investigated by Warburg¹⁻¹⁰ are convenient for general use. Self-integrating actinometry for specific purposes, valid even in polychromatic light, has been exemplified by Dorcas and Forbes.⁹⁵

Photogalvanic Cells involve too many obscure phenomena to promise well as actinometers. None the less some use of them has been made.⁹⁶

Selenium⁹⁷ and Thalofide⁹⁸ cells have sensitivity peaks at the longer wave-lengths, and other drawbacks for photochemical work.

Intensimeters practically non-selective^{115, 99; 11, pp 1534-44} produce thermal or electrical effects. In the thermal group the radiometers with vanes^{100, 101, 102}, torsion radiation balance¹⁰³, thermophotometer¹⁰⁴ and radiocalorimeter^{105, 106} and in the electrical group the microradiometer¹⁰⁷ and radiomicrometer¹⁰⁷ all leave something to be desired in range, or convenience or simplicity of interpretation. The thermopile^{100, 108, 109, 111, 112} and the bolometer^{100, 108; 109, p 171; 111, 113}, have preempted the photochemical field, and both can be made in the linear or the surface form^{4, p. 875}. The building and operation of the bolometer requires more technical information. The linear thermopile with a very thin quartz window, not exhausted, is robust, convenient and gives a relation almost linear between intensity and galvanometer deflections^{108, p 50}. For accurate work this relation should be plotted, and the zero kept at a fixed point on the scale. By taking readings in a number of positions and integrating graphically the linear thermopile serves the purposes of the surface form. Following the detailed directions of Coblenz^{100, 108, 109} thermopiles can be constructed and mounted by anybody having good eyes, a steady hand and considerable patience. Full directions for installation and use are given also. Several constructed in this laboratory, 30 to 40 × 1 mm. in area and having resistances between 15 and 20 ohms have given excellent service. They have about two thirds the c.m.f. of the newest Hilger thermopiles and the deflections of the two types stand in a very constant ratio throughout the spectrum. At high intensities, shunt resistance, s , and series resistance, a , are provided. A serviceable relation is $s = p(p - a)/a$, where p is the resistance of the pile. Moll^{110, 114, 115} and Burger have described vacuum thermopiles with exceedingly thin junctions. While too sensitive for ordinary photochemical purposes, they should prove useful in determining the spectral energy distribution of false light delivered by a monochromator.

Galvanometer^{100, p. 415; 108}. With thermopiles described above, a d'Arsonval galvanometer of resistance 15–20 ohms and sensitivity 15 mm/mv¹¹⁶ will be satisfactory. The new loop galvanometers^{116a} are very sensitive. Owing to drift, it is difficult to measure the e. m. f. of thermopiles by potentiometry using the galvanometer as a zero instrument. If a Julius suspension is necessary to eliminate vibration, a heavy slab can be made of reinforced concrete. The scale support is cut from a thick board with the proper curvature, the mirror being at the centre of curvature. Millimeter scales, with numbers written as mirror images, are tacked on. A row of small electric bulbs with a shield of bright tin plate is placed in front.

Radiation Standards and their Use. Of the various standard flames described^{117: 17, p. 442} the Hefner lamp^{117, 118, 119, 120} is most often used as a total radiation standard. In defining such standards the assumed value of the black body constant^{117, p. 88} should be mentioned. More convenient are the standard carbon lamps,¹¹⁷ with certificate and directions for standardizing thermopiles, ordered from the Bureau of Standards. Two should be used successively in crucial comparisons. Only standard models of ammeters can be used. In particular, overloading must be avoided. A separate calibration curve may be established for each shunt-series resistance, and then all can be combined into one by proper reduction factors. The conditions of standardization and use must agree closely.

To standardize the thermopile for intensities higher than those corresponding to the highest rated amperage of the lamp at the standard distance of two meters the distance is cut down and another set of readings taken for the same amperages. The deflections at the lower current strengths and the lesser distance are interpolated upon the standard curve, and the corresponding energies incident upon the thermopile are found. The ratios of these to the energies at standard distance with equal currents are averaged. The average ratio times the energy for any other current at the standard distance will give the energy incident upon the thermopile at the shorter distance, and the

energy-deflection curves are extended accordingly. No assumption is made, in the process, concerning the relation between intensity and distance.

Spectral Energy Distribution of Light Sources^{120a} may be roughly worked out by surface integration of a spectral energy curve taken with a spectroradiometer or monochromator having a narrow slit; correction for slit width must be made^{120b; 121; 115, p. 287}. Corrections for aberrations, reflection, absorption, and scattering in the optical train would be desirable, especially in the ultraviolet. Absurd errors result from uncorrected surface integration of such diagrams made with a wide slit. Fabry and Buisson¹²² measured total energy L transmitted by n different filters, of thickness d (or n different thicknesses of the same filter). They solved n equations of the form $L = A_1 e^{-m_1 d} + \dots + A_n e^{-m_n d}$ for A_1, \dots, A_n the n monochromatic intensities of the original source. Of course m_1, \dots, m_n are determined separately for each filter. It is hazardous to assume that two sources of the same type, especially mercury vapor lamps¹²³, have the same spectral energy distributions even if dimensions, electrical conditions and the like are comparable^{53, 54}. The photochemist seldom needs to know the spectral energy distribution of the source itself, as he is primarily interested in monochromatic intensities at the exit slit of his monochromator or behind filters. Indeed he could interpret the total effect of polychromatic light only as a sum of monochromatic effects¹²⁴. The difficulties of such comparisons will be inferred from a study of the literature^{21, p. 342; 125, 126}.

Polychromatic Light acting directly upon a sensitive system produces a total effect which is a highly complicated integral¹²⁴ involving spectral energy distribution of the source, absorption coefficients of reactants, products and perhaps of solvent or other substances, concentrations, thickness of layer, quantum yields, time and temperature. Its chief value is to detect photochemical reactions, sensitizers, catalysts, inhibitors, to study concentration effects involving non-absorbing (dark) reactants, and in some (though perhaps not all) cases to investigate temperature coefficients and the reciprocity law. Some quantitative information may be gained regarding the above by instituting comparisons, throughout which the source, the thickness of the absorbing layer and the concentrations of all absorbing substances are practically constant. Obviously these conditions forbid the transformation, during any experiment, of any considerable fraction of any absorbing substance unless all absorption coefficients are measured, or unless the sensitive reactant

absorbs all the light at all stages of the reaction. On the other hand those who delight in "unimolecular constants" have only to start with a mixture which absorbs but a small fraction of the actinic light.

Quantum Yields in Polychromatic Light may be very crudely estimated as follows: The total radiation incident upon the cell face is calculated from the total wattage of the source and the inverse square law, or from thermopile measurements. Concentration and thickness of layer should be sufficient to insure complete absorption of actinic light. Only one absorbing substance should be present. Some arbitrary fraction of the total radiation can be assumed to be actinic. Better, the actinic region is located by trial with filters of given transmissions, and laid off upon a spectral energy diagram of the source, which must include all the infra-red. The ratio of the two areas times total energy is actinic energy absorbed. Average quantum yield follows from the latter, average frequency, and number of molecules transformed (with correction for dark reaction if any). It must of course be proved that no two spectral regions used cause the reaction to proceed in opposite direction^{127, 128}.

Light Filters^{11, p. 1529-34; 12, p. 694-6}. The sum total of data on light adsorption is very great, but relatively few of the systems would make good light-filters. The substance must be definite, reproducible and fast to light even if warmed up. If colloidal, its absorption coefficient must also be unaffected by dilution, by lapse of time or by any substance added. Many dyestuffs^{129, 130} fail to meet these specifications. If oxidizable, as ferrous solutions¹³¹, it must be covered by a suitable liquid. Transmissions, including the container if any, must be known or determined by the investigator for each wavelength of significance. When data on thin sheets are given, small variations in thickness are serious. The methods and precautions of spectrophotometry are given in Dr. de Laszlo's report. If non-selective intensimeters are to be used behind filters, infra-red transmission must not be forgotten. Keyes¹³² interposes a vacuum cell as a protection against the heat of the lamp. A quartz water cell 1 cm. thick transmits 58% at 945 m μ and 14% at 1190 m μ ¹³³. Coblentz has suggested filters to absorb infra-red completely^{134, 135}.

Spectrograms of light sources taken through filters give little quantitative idea of the transmissions of the latter because it is impossible to make due allowance (except by the method of Luckiesh^{16, p. 182}) for spectral energy distribution of the source¹³⁶, sensitivity curve of emulsion, characteristic curves of the plate at different wave-lengths, and the effects of reproduction processes.

As filters have at best rather broad transmission bands, they should be used with discontinuous sources having strong emission lines nearly coincident with their respective transmission maxima. Some filters have a narrow absorption band which blots out one line of a particular source. The didymium filter, glass¹³⁷ or solution, absorbs the yellow line of the mercury vapor lamp, transmitting the green. Unfortunately such coincidences are rare.

Gaseous Filters^{16, pp. 36-45}. While nitrogen is transparent even at 125 m μ ,^{16, p. 36} oxygen absorbs from 186 m μ ^{16, p. 36}, a fact which prevents the shorter wave-lengths from exerting their striking photochemical effects except at

very short distances from the source^{138, 139}. Calcite, also, has been used to intercept these.¹³⁸ If the ozone formed by mercury vapour lamps is not removed by a gentle current of air, radiations between 230 m μ and 280 m μ will suffer to some extent.¹³⁹ Dr. A. L. Marshall has suggested to the author that mercury in pumps or manometers may introduce enough vapors to cause trouble in working with resonance radiations (1) by opacity (2) through excited atoms. The most useful of the gaseous filters contain bromine and chlorine^{140, 141} or chlorine¹⁴² in quartz and transmit λ_{254} . Villars¹⁴³ finds the Peskov filter more nearly monochromatic.

Liquid and Solid Filters ²⁶, vol. 3. Lack of space forbids any attempt to review critically the data as a whole. The variety of ultraviolet filters is inferior to that for visible, also the information about them. Certain glass filters and dyes were carefully measured up by the Bureau of Standards ^{144, 145} including monochromats for mercury vapor lamps. Commercial filters include Agfa, Corning, Cramer, Fuess, Ilford, Jena, Maison Calmels, Wratten. Potapenko¹⁴⁶ gives complete directions for making gelatine-dye filters. Wood's nitrosodimethylaniline¹⁴⁷ filter transmits the long ultraviolet only. Hood¹⁴⁸ describes glasses with rather extraordinary transmissions. Lists of filters are given in a number of books ¹¹, pp. 1529-34; ¹², pp. 694-6; ¹⁵, pp. 78-84; ¹⁶, pp. 46-92; ¹³, pp. 72-75. Nickel oxide glass (Corning Glass Works) transmits 366 m μ .

Procedures with Light Filters, if qualitative, require no extended comment here. Outfits including lamp, case, also holders for sheet filters and quartz or glass cells are advertised. In the absence of a monochromator, or with cells having large surfaces, a thermopile can be read, in several positions, between filter and cell and behind the cell. If radiometer is non-selective, the infra-red radiation absorbed by the solutions must be considered. Noddack²⁷ de-

scribes a typical apparatus. Correction for reflection^{8, p. 1239} can be made as described below. Reflected infra-red might erroneously be reckoned as a part of the actinic light absorbed. Such a method would work well using for instance a mercury vapor lamp, with filter 86 of Gibson, Tyndall and McNicholas¹⁴⁴. The line at $366\text{ m}\mu$ ^{145b} is very strong and well isolated and would be transmitted almost free from contamination. On the other hand, the weak line at $302\text{ m}\mu$ could scarcely be separated effectively from the strong line at $313\text{ m}\mu$.

General Methods for Monochromatic Light. Low-voltage arcs deliver monochromatic resonance radiation of low intensity¹⁴⁶. That evoked in cold mercury vapor by transverse illumination from a mercury vapor lamp^{150, 151} is about one fortieth as intense in $\lambda 254\text{ m}\mu$ as the source¹⁵⁰, and has possibilities for practical work.

Ruled gratings are light-weak,¹⁵² but would be the only obvious expedient for monochromatic photochemistry in the Lyman region. A monochromator based upon Priest and Gibson's rotary dispersion colorimeter¹⁵³ is imaginable. Focal isolation, so successful in infra-red work¹⁵⁴ was used by Andrews^{15, p. 83} to separate visible from invisible and by Terenin¹⁵⁵ for different ultraviolet regions. Professor F. A. Saunders kindly tried out the method with the author, but spectrograms of the ultraviolet showed much false light over a range of $100\text{ m}\mu$.

Monochromators employing refraction dispersion are at present relied upon for the best practicable compromises between intensity and monochromatic purity. Both improve with the size and optical refinements of the outfit.

The simplest type is a slit-shaped source at some distance from a prism, then a lens and a movable slit. In practice a collimating lens is added, as well as other optical parts. The beam is usually horizontal, but may be made vertical¹⁵⁶.

If a ready-made instrument is to be purchased, objectives less than 5 cm. in diameter are of limited usefulness in the case of weaker lines. The suggestion of Fabry¹⁵⁷ that any spectroscope plus an exit slit is a monochromator was hardly intended for photochemists.

A great variety of suitable prism monochromators has been described.

"Home-made" Monochromators are relatively inexpensive, and if carefully constructed will prove very satisfactory. Dr. Villars of this laboratory has briefly described one⁶⁹ having a fused quartz prism $105 \times 105 \times 105 \times 80$ mm. Certain of the following suggestions were made by him or by Dr. P. A. Leighton of this laboratory. The above literature will suggest many variations.

The necessary rigidity may be had by using a slab of soapstone drilled for bolts or reinforced concrete poured around the various supports. Several front slits are provided, with increasing widths, and curvatures sufficient to neutralize distortion of the emerging beam at various wave-lengths¹⁷¹⁸; the flat side of the bevel is toward the source. A constricted mercury vapor lamp can be bent so that its luminous column will have the average curvature of the slits. In this way vertical intensity gradients in the emergent beam are avoided. With most other light sources a quartz condensing lens of the type used in removing picture projectors can be used. Lenses figured to remove spherical aberration¹⁶² are preferable. Nickel or silicon¹⁷² spherical concave mirrors, though changing the spectral energy distribution of the source, have no chromatic aberration and can replace the lenses^{165, p. 103}. The rays should not be too far from perpendicular incidence. A fused quartz prism, 60° , and one of extra heavy flint $N_d = 1.69$ make an excellent outfit. Co-blentz¹⁷³ has reported on the optical constants of lens and prism material. Fig. 1, kindly prepared by Mr. W. G. Leighton of this laboratory shows the distribution of wave lengths on the focal plane of a monochromator for four different materials. The high dispersion of water¹⁷⁴ from $250 \text{ m}\mu$ has suggested a hollow quartz water prism.¹⁷⁵ The lenses will usually be made of fused quartz. Striae can be seen between crossed nicols or by other methods¹⁷⁶. Combinations with fluorite or even water removes chromatic aberration. A prism table with lens taken from a small discarded spectroscope can be made over for larger units. A special table must carry the exit slit (of variable width) along the focal plane; it holds an exchangeable mounting for thermopile behind it, and another mounting for thermopile^{109, p. 154} still farther back. This last mounting can be moved across the light beam by a thread with millimeter pitch. Various automatic devices are suggested to keep the above system perpendicular to the light beam^{55, 168}. The parts are set up by trial, using a screen soaked in alcoholic anthracene^{11, p. 1256}. Collimation and minimum deviation at $\lambda_{366} \text{ m}\mu$ will usually suffice for other wave-lengths.

To set the exit slit squarely on a given line the position of maximum galvanometer deflection is found, or spectrograms of the emerging radiation^{4, p. 874} are made with an auxiliary spectrograph.

The emergent light may be made parallel or less divergent^{2, p. 221} by an additional lens. This greatly diminishes the light incident upon unit area of cell face, and cuts down percentage accuracy of thermopile readings. Also, a greater mass of reactant is needed to absorb a given amount of energy, which

FIG. 1

magnifies analytical errors. To meet this difficulty Villars used a cell of trapezoidal cross-section placed close to the exit slit. The glass sides diverged at the same angle as the emergent beam of 366μ . The front quartz window was only slightly wider than the exit slit used.

Instead of integrating the light with a surface bolometer^{1, p. 749} or thermopile, Villars⁵⁹ read his linear thermopile in about ten positions behind his cell, and made a graphical integral of intensity and area. He has shown mathematically¹⁷⁷ the propriety of measuring absorption coefficients in an analogous fashion. It is possible at least to halve the minimum error of 10% given by v. Halban^{164, p. 224} for absorption measurements by thermopile except for a

weak line near a much stronger one. The thermopile should cover the whole beam in a vertical direction, or else an integration vertically should be attempted.

Complications are introduced by fluorescence^{86 p 227} and by turbidity^{178, 179}. The method of Plotnikow^{14, p. 154} for continuous removal of precipitates is not intended for quantitative work. Changes in absorption may occur when gases^{5, p. 239} or solutes^{178, p. 321, 359; 178a} are mixed. Lambert's law should be proved to hold before assuming that the absorption coefficient varies with concentration. If two or more substances absorb light, this must be properly apportioned¹⁸⁰ between them, whether reactants or products, at each stage of the reaction. Water must be taken into account at the shorter wave-lengths, especially if the solute has small absorption; Kreusler's figures¹⁸¹ are not based upon a unit layer. Warburg^{8, p. 1230} gives the proper corrections for reflected light; v. Halban and Ebert¹⁷⁸ describe a more refined correction for light absorbed and reflected by the vessel full of solvent. Absorption by good quartz is negligible to 250 $m\mu$ at least,¹⁸² but a small trace of iron tells a different story. The thermopile deflection at 254 $m\mu$ should not be decreased by more than 8 per cent by interposing a 1 cm. water cell. At 207 $m\mu$ absorption by quartz becomes perceptible^{4, 47}.

False Light^{184; 18, pp 203-7}. The purity of monochromatic light, $\lambda/\Delta\lambda$, may attain 10^6 in extreme cases,¹⁸⁷ but no such refinement is attempted in photochemical work. The degree of monochromatism which is necessary to attain a given degree of accuracy in a quantum yield will vary greatly with the system under consideration. If the photochemical efficiency ϕ reckoned in molecules per erg is practically constant over a given spectral region, the false light in the same region is equivalent to that of the principal wave-length. The error is worst for a weak line, near a strong line, in a region where $d\phi/d\lambda$ is large. Kuhn¹⁸⁵ required 2 to 2.5 quanta per molecule of ammonia over the interval 202.5 $m\mu$ to 214 $m\mu$, but when a second prism was added and only the lines 206.3 $m\mu$ and 210 $m\mu$ were transmitted, no reaction at all could be directly observed. One may not agree with Kuhn's contention that the ammonia molecule must first absorb $h\nu$, and then $h\nu'$ not coinciding with any frequency absorbed by the normal ammonia molecule. But his findings should give pause to all those who work with imperfectly resolved light, especially when gases are involved.

Thermal radiators, especially, emit an amount of infra-red large in proportion to the light at shorter wave-lengths. Coblenz¹⁸⁶ has emphasized the importance of taking occasional thermopile readings behind a shutter of electric smoke or Corning red glass, and subtracting the indicated correction. False light in other spectral regions can be cut down by using a narrower monochromator slit, or a double monochromator^{159, 167} which squares (roughly) the fraction of the false light. If Lambert's law holds over a considerable range of thickness of layer of any given absorbent, the degree of monochromatism is probably good.^{178, p. 331} Filters used with monochromators cause a loss in intensity which magnifies the effect of analytical errors without necessarily making the monochromatism much better. Warburg^{6, p. 322} also Villars,⁵⁹ set up an auxiliary spectrograph with a narrow slit behind their exit slits, and examined the spectrogram for false light without attempting a quantitative correction. To make this, such a spectrogram could be taken after each photochemical experiment, measured up on a densitometer and relative intensities estimated at suitable intervals after some correction for change in photographic density with wave-length.⁹¹ The relative intensities could be more directly found by an auxiliary spectroradiometer. These would next be plotted for each position of the exit slit, on the same wave-length scale as that of the auxiliary spectrograph. The "pure light" would be arbitrarily marked off from the "false light," and the ratio between the two areas determined by graphical integration. The thermopile reading for the corresponding experiment would be accordingly corrected. Next the ordinates on the above curve would be multiplied by the uncorrected photochemical efficiencies found for the corresponding wave-lengths. Finally one would mark off the areas under the new curve corresponding to "pure light" and "false light," and deduct the latter from the total photochemical reaction, after correction for any dark reaction. A cruder method of correcting for false light, when using light filters, has been described by Luther and Forbes.¹⁸⁷

Polarized Light. Ghosh states that circularly polarized light has a slightly greater photochemical action upon solutions than unpolarized light of equal intensity^{188, 189}. Weigert^{190, 191, 192} finds that polarized light produces changes in light absorption by certain solids.

Solids^{12, p. 738; 22, p. 224}. Methods for photochemical study of solids may be found from the references given. Plotnikow^{14, p. 144} formulates the progress of the reaction zone in gelatinized media where a colored reactant is decolorized by light without convection^{14, p. 144; 196}.

Stirring. Warburg⁸, p. 1235 found that the speed of photolysis of potassium nitrate was the same whether the solution was stirred or not. In this case the absorption was not high, and the reaction was slow. On the other hand, stirring was indispensable when a mixture of maleic and fumaric acids⁹, p. 960 was irradiated because absorption was high and the speed of isomerization considerable. These principles are generally applicable. It would be superfluous to recount here all the types of stirrers for liquids, including gas bubbles. Warburg⁷, p. 300 shows how to keep a gas-stream well mixed while passing through a light-beam. If the stirrer is opaque to the radiation there must be corrections for its volume and for the shadow behind it. If transparent, one corrects only for the "hole" made in the reaction mixture, unless absorption is complete anyhow.

Temperature Regulation is now²¹, p. 346-8 believed to be less important than formerly,¹⁴, pp. 62-72 unless there is a considerable "dark reaction." The temperature coefficients of photochemical reactions proper seem to be small. Much ingenuity has, however, been expended on "light-thermostats," few of which would be suitable for monochromatic work. Running water,¹⁹⁷ water-cooled flasks,¹⁹⁸ liquid thermostat with glass walls,¹⁹⁹ stirrer of coiled tube through which chilled brine circulates,¹⁸⁷ airbath and fan, transparent vapor or liquid baths,²⁰⁰ envelope of refluxed naphthalene,²⁰¹ electric ovens^{200, 202, 203} are typical devices.

Dark Reaction Velocity. This is determined inside or outside of the reaction vessel by the usual methods. If the dark reaction is important all work should be carried out at the lowest possible temperature, and the reaction layer should not absorb more than half of the incident light. Wegscheider¹²⁴ points out that the photochemical reaction is not the difference between total, and dark reaction determined separately. The error in such an assumption would be negligible, however, if total reaction is small in comparison with amount of reactant initially present. If the temperature is not constant during exposure to light, the temperature coefficient of the dark reaction may have to be measured, and the total dark reaction found by summation for a number of short time intervals.

Calculation of Results. Wegscheider¹²⁴ gives various equations for reaction velocities, and integrals, developed exclusively from the standpoint of dark reactions. He compares his deductions with those of Plotnikow,¹⁴ taking issue with him upon certain points¹⁸³. Warburg¹⁻⁹ was the first to make adequate calculations of quantum yields⁸⁹; he included all the important cor-

reactions except that for false light. Allmand's report²¹ summarizes recent conclusions based on observations of reaction velocities, while the Oxford symposium¹²⁶ is concerned primarily with quantum yields. These two methods of formulating photochemical reactions are supplementary,^{21, p. 344} and are interconvertible when complete quantitative data are available for monochromatic intensities, absorptions, concentrations and quantities transformed during given intervals. The less complete such data are, the more cautious must be any interpretation, and the more commodious the holes provided by the author for his own escape.

¹²³ Wegscheider: *Rec. Trav. chim.*, **44**, 1118 (1925).

Analytical Methods are chosen with reference to their probable errors and with reference to the quantity of product which can be formed with the given light source in the time available. Time may be limited by a rapid dark reaction or by laboratory conditions. To form a millimol of product, for instance, with unit quantum yield at 366 $m\mu$, 3.3×10^9 ergs must be absorbed. If the intensity is L ergs/sec and n the number of millimols needed, the time will be $n \times 9 \times 10^5/L$ hours (assuming complete absorption). A brand-new commercial mercury vapor lamp of standard type, run on 2.2 amperes and 10 volts/cm will deliver at an exit slit 40×1 mm, of a monochromator with 50 mm. objectives and an aperture ratio 4.5, 8×10^3 ergs/sec at 366 $m\mu$, and 4×10^3 ergs/sec at 280 $m\mu$ where the quantum is nearly a third greater.⁵⁷ (Therefore the exposure times per millimol would be 110 and 3000 hours respectively.) The other important wave-lengths of the lamp have intensities between the two extremes. The time necessary to get n millimols would be increased by unfavorable quantum yields or by low absorptions. These considerations show why Boll¹⁵⁶ despaired of doing monochromatic work with a mercury vapor lamp if he had to determine the product by chemical analysis. Bodenstein and Lüttkemeyer²⁰¹ used the full radiation of the tungsten arc to study hydrobromic acid formation "as dispersed or filtered light would have taken too long." Instances of this sort could be multiplied.

The constricted mercury vapor lamp without its maximum overload⁵⁷ will give ten times the slit illumination of the commercial lamp. Sparks from a 4 KW transformer^{10a, p. 137} give and 2×10^4 ergs/sec at 207 $m\mu$. It is difficult to increase monochromator intensities much beyond such values.

Chemical methods in such special cases as iodimetry^{2, p. 222} or electrometric titration¹⁶⁹ give with a small fraction of a millimol an accuracy of a few percent, which is the probable error of determining intensities. If a cylinder or bulb is fused to the top of the light reaction vessel the titration can be completed without transfer of the contents. Pregl's microchemical methods²⁰⁵ are suggestive to the photochemist. Gas analysis using chemical absorbents²⁰⁴ may suffice. Warburg^{3, p. 764} has stressed the importance of rapid removal and determination of unstable products, making correction for the fraction lost.

Certain physical methods^{11, p. 1492-6} of analysis require small amounts of substance. They are indispensable when chemical methods change the concentration of the substance to be determined or when a number of measurements must be made without heavy inroads upon the reaction mixture.

For gas reactions where the number of molecules changes one can use the quartz manometer with flattened tube,²⁰⁶ the quartz thread manometer,²⁰⁷ or the various manometers containing mercury^{1, p 746} or other liquids. Hydrogen has been determined manometrically after condensing chlorine and hydrogen chloride in a side tube by adequate refrigeration.²⁰⁸ Such a method is particularly useful when the number of molecules does not change. Light absorption measurements,²⁰⁹ if feasible, are advantageous. For liquids also absorption measurements have been used.²¹⁰ Conductivity^{9, 156, 211} and potentiometry²¹⁰ are very sensitive. The fluorescence change in ultraviolet light²¹² has been suggested as a means of following concentration. Photoelectric effects have been employed^{213, 214}.

Reaction Vessels. For quantitative work the faces should be plane, and perpendicular to the light beam. Warburg¹⁻⁹ developed in a high degree the cylindrical cell with plane parallel ends for liquids, and for gases in rest or in flow at pressures from 1 to 400 atmospheres. He used a lens behind the opening in the focal plane to make the rays parallel.^{2, p. 221} It was necessary to fill the cell with radiation when an unstable product such as ozone was flowing through it. The trapezoidal vessel for use in diverging light has been described above.

Crystal quartz must be cemented or clamped, but fused quartz cells cylindrical, rectangular or trapezoidal can now be made either in the oxyhydrogen flame or by applying in powdered form a flux slightly more fusible than the quartz and fusing the joints together all at the same time in an electric furnace. A new glass has recently been described by Hood¹⁴⁸ which would be serviceable down to 200 m μ , and which can be had in sheets several inches square. More information concerning its resistance to chemicals would be welcome. Other promising glasses are said to be in process of development. Cements^{12, p. 693; 235} should be avoided if possible, but they will give good service if intelligently selected. Warburg^{9, p 960} ground his surfaces accurately and found that the thinnest film of paraffin, with a clamp, was sufficient. Fused silver chloride, used as described by Hulburt²¹⁵ makes good joints between quartz and glass, and graded seals are possible. Other cements that have been found useful are fish glue, gelatine and concentrated acetic acid, wax and colophonium, "picein" (a German product), de Khotinsky, lead oxide and glycerine,²³⁵ lead borate and various dental cements.

Spherical vessels should in general be avoided, and cylindrical vessels illuminated perpendicular to their axis are unsuitable for quantitative work. Formulas for absorption in the latter¹⁴, p. 155 are not corrected for reflected light. Concentric annular vessels, one of which may be a mercury vapor lamp²¹⁶ and another a light filter¹⁸⁷ or a water cooler²¹⁷ constitute very compact and efficient systems, especially for qualitative work, and make it possible²¹⁸ to use the shorter ultraviolet, which is absorbed by air.

Among recent specimens of apparatus for investigation of gases include one of Coehn and Jung²¹⁹, the whole of which could be heated to the softening point of glass to remove adsorbed gases, also one of Marshall^{219a} which could be baked in a furnace at 300° to 400° for the same purpose while passing electrolytic chlorine. Norrish and Rideal²²⁰ devised a train for mixing hydrogen, chloride and oxygen in any proportions, dried with pentoxide, and measured manometrically. Porter, Bardwell and Lind²²¹ realized a valid comparison of hydrogen-chlorine mixtures of equal sensitivity subjected to light and to radiochemical action.

Special Procedure with Gases. Intensive drying has been discussed at length in the literature²¹, pp. 349, 368; **11**, pp. 1557-60; 222, 223. The Budde effect has been unraveled by Lewis and Rideal.²²⁴ Weigert and Kellermann²²⁵ have devised a most ingenious apparatus for taking many photographs of the Draper effect during the initial 1/40 second of exposure. Coehn and Heymer²²⁶ have followed the hydrogen-chlorine reaction in a jet from which the gases emerged into an atmosphere of hydrogen, to eliminate effects of contact with walls.

Of extreme importance in photochemical theory and practice are the reactions initiated by rayless collisions with excited atoms or molecules²¹, pp. 361-367; 226a. Experimentation with excited mercury vapor has developed some special types of apparatus²²⁷.

ABSORPTION COEFFICIENTS

BY HENRY G. DE LASZLO*

A great divergence of views¹ as to the exact mechanism of absorption in photo-chemical reactions still exists. We shall understand this mechanism better if research be undertaken on the absorption spectra of each of the several components of the reacting system, be it in solution, or in gaseous phase. These spectra should be measured quantitatively, i.e., the exact positions of the absorption bands in the spectrum and their absorption coefficients should be determined accurately before commencing a study of the reaction. This might give a clue as to why for a given reaction, light of one wave-length is photo-chemically active, and inactive if of another wave-length. Until very recently, absorption coefficients have only been determined for solutions or pure liquids. These will therefore be discussed first. The methods may be divided into two classes, A and B.

(A) In general, photographic methods are the best and nearly all of them depend on the following principles:

A common light-source, which is usually an iron spark, is optically divided into beams of equal intensity I . One (a) passes straight into the spectrograph and the other (b) reaches it after having traversed the solution. Now if by some means (a) can be varied equally throughout the spectrum with one of the methods cited below, or if the time of exposure t be changed for any given concentration one would be able to find some position (λ) common to the two spectra where the lines are of equal intensity. This is plotted against the corresponding absorption coefficient Σ .

The molecular absorption coefficient Σ is calculated from the relations $I = I_0 \cdot 10^{-cd}$ where c is the molecular concentration and d the thickness of the solution or gaseous layer, I being the intensity of the light before entering the solution and I_0 the light after traversing same. Since I is proportional to t ,

the time of exposure for a given photographic effect, then $\Sigma = \frac{xc}{d} \cdot \log \frac{t}{t_0}$.

x is the constant for the photographic emulsion used, and lies between .8 and .9. Thus we see that either I or t may be varied.

There are a variety of ways of changing I and they may be roughly classed as follows:

- I. Varying distance of the light source.
- II. Diaphragm in path of rays.
- III. Absorbing medium.
- IV. Nicol prisms.

* Research Associate, Massachusetts Institute of Technology.

¹ Trans. Faraday Society, 21, 438 (1926).

I. This is usually the most accurate and theoretically correct method, but it is difficult to carry out in practice. Schaefer has, however, developed it and the apparatus can be obtained from Zeiss-Jena.²

II. Sectors

An equipment for visual spectrophotometry has recently been adopted by Guild.³ This method uses a rotating sector with variable aperture and depends upon the validity of Talbot's Law as shown by Hyde.⁴ Many experiments have shown that the latter holds to within the accuracy of the best photometric measurements down to quite small angular apertures. The original sector photometer was introduced by Hilger in 1913, and has been mostly used in conjunction with quartz or glass spectrographs.⁵

An improved form of sector photometer was originated by Judd Lewis,⁶ but the apparatus is both expensive and difficult to keep in adjustment, though very rapid in use. When using the photographic method, it is best to use only two sets of exposures, and one aperture of the sector, at the same time varying the thickness of the solution layer. This sector method can be used throughout the visible and ultra-violet regions and gives very accurate curves.

Wire Screens

Winther⁷ describes the method of reducing I by means of blackened wire screens placed in the path of one of the beams. These screens are perfectly achromatic and any reduction of I can be obtained by varying the spacing and thickness of the wires. A set of screens can thus be made to cover any range of Σ .

III. Merton⁸ uses a sheet of quartz upon which a platinum wedge has been cathodically deposited. This is found to be entirely non-selective in its absorption and can be calibrated accordingly, and then placed in the path of one of the light beams.

IV. Most of the methods for investigating the visible spectrum are of this type. The König-Martens spectrophotometer enables Σ to be determined for each λ . It has been both universally applied and frequently described.⁹

A spectrophotometer has recently been constructed by Bellingham and Stanley.¹⁰ They use nicol prisms of special construction which are transparent down to the limit of calcite 2500 Å. It is attached straight onto the slit of a spectrograph and as in II employs the juxtaposition of two spectra. It is perhaps more accurate than the sector photometer owing to the difficulty of cutting sector openings accurately. Its shape, however, does not allow of having solution layers thicker than 5 cms.

A method whereby the light intensity is kept constant, and the time of exposure and concentration being varied, has been used for many years by Victor Henri.¹¹ Henri's photographic method is applicable over the whole range of 8000-2000 Å using a glass spectrograph for the visible, and a Hilger quartz E-2 instrument for the ultraviolet. It is simple and its accuracy has been rigorously tested.¹² The author has used it for many years, and the following refinements may prove useful. A light source of unvarying intensity is a prime necessity to insure accuracy. We use a 2 mm. spark between iron electrodes (8000-2500 Å) and copper for the range 2500-1900 Å, quenched by a synchronous rotating gap to prevent arcing and assure constancy. Solutions of known molecular concentration are made up in optically pure hexane,¹³ alcohol or ether. A Baly absorption tube constructed of fused quartz with the inner tube ground into the outer like a hypodermic syringe is then filled with the solution. A similar tube is filled with the pure solvent. The spark spectrum after having traversed a thickness d of the solution for a time t is photographed with the spectrograph using a slit height of 1-2 mm. After moving the plate carrier down a distance equal to the spectrum width a second exposure for time t_0 (5-10 seconds) is made through the same thickness d of solvent. A metol-hydroquinine developer is used. A Leitz-Metz¹⁴ binocular microscope with a magnification of $25\times$ may be employed without eye-strain for identifying the lines of equal intensity for each set of exposures in which d is constant. By varying t , d , and c , the Σ corresponding to any λ can be determined to $\pm/\text{Å}$ and is plotted against $1/\lambda$.

To supplement the above methods a continuous source of light should be passed through the solution in order to locate intensity maxima of the smaller absorption bands. A gas-filled tungsten^{15, 16} lamp is satisfactory down to 3000 Å, or a high frequency spark^{17, 18} under distilled water between duralumin or copper electrodes, using the iron spark as a standard, covers the whole spectrum down to 2000°A.

(B) *Photoelectric Cell and Microphotometer Methods.* Direct reading methods consist in using a thermopile or photoelectric cell instead of the eye in conjunction with some form of constant deviation spectroscope to act as a monochromator. Thus a direct measurement of light absorbed for each wavelength may be made by noting the galvanometer or electrometer deflexion before and after traversing the absorbing medium. The most accurate work

There are a number of other methods of Spectrophotometry in the visible region which are well described in the J. Opt. Soc. America, 10, 170 (1925), and in Bur. Bur. Standards, 18, No. 440 (1922); Weigert: Ber., 49, 1496, 1530 (1916); Jones: J. Opt. Soc. America, 10, 561 (1925).

has been that of Halban and his pupils,¹⁹ who extended their observations throughout the visible and ultra violet portions of the spectrum. Gibson²⁰ has developed a null method which seems promising, but until now has only been used for the visible region.

Photographic^{21, 22}. Here a constant beam of continuous light is passed through the solution onto a spectrograph for a known time. The same exposure is repeated without the solution, the spectrum being in juxtaposition to the former. This is followed by an iron comparison spark.

The absorption will be clearly seen on the continuous background and is measured in some form of direct reading microphotometer^{23, 24} using either nicol prisms of neutral tint glass wedges to obtain a matching of photographic density. Automatic registering^{25, 26} photometers are the most convenient. In all cases the instruments may be directly calibrated in Σ beforehand by means of some known substance.

The Determination of the Absorption Coefficients of Vapors and Gases has been much neglected until very recently. Considerable work has, however, been done by Henri and his pupils in measuring the exact position of absorption bands and their fine structure. For substances with high vapor²⁷ pressure at 70°C we use tubes of fused quartz into which, after evacuation, a small amount of the vapor is allowed to enter. By varying the pressure and passing continuous ultra-violet light through the tube for the same length of time t , we get a complete curve showing all fine structures with comparative data as to their absorption coefficients. The latter may be more accurately determined by methods similar to solution spectra using an iron spark. For substances with a very low vapor pressure at 20°C we use quartz tubes of a special design electrically heated throughout a wide range of temperatures. The exact values for Σ may be found by inserting weighed quantities of substance into an apparatus consisting of a number of quartz absorption tubes of known total volume and of varying lengths connected to a common reservoir. We then will know the number of gram-mols per litre and hence from the time of exposure and thickness of layer can calculate Σ for each λ .

The same system may be adapted for bodies with low V.P. by making the apparatus smaller and inserting all but the reservoir in a furnace which is heated to the highest temperature to be used in the experiment. The reservoir is heated in a separate furnace whose temperature can be accurately measured and may be raised in steps, photographs being taken at each step through each of the several tubes. Such a series of photographs will again give us exact data as to both Σ and the position of the bands.

THE EXCITED SYSTEMS FORMED BY THE ABSORPTION OF LIGHT

BY LOUIS A. TURNER

The law of Photochemistry which has been known the longest and is the best-established and the most fundamental, is that of Grotthuss and Draper, viz., that the only radiation which will produce a photochemical reaction is that which is absorbed by the reacting system. The process of absorption is, therefore, of primary importance and any generalization concerning this process should be of some importance for the photochemist. Some of the newer developments of the theories of atomic and molecular spectra and their relations to the structure of atoms and molecules are concerned with the various possible processes of the absorption of light and the properties of the excited systems produced by that absorption. This article will be devoted to a brief discussion of such of these results as may have some bearing on photochemical reactions.

The two principal postulates of Bohr's theory of atomic and molecular structure which has been so successful in correlating the spectroscopic phenomena are:—1) A molecular system can exist only in certain stationary states having definite energies and 2), when the system changes from one of these stationary states of greater energy to another of lesser energy monochromatic radiation is emitted, its frequency being given by the relation $h\nu = E_1 - E_2$. ν is the frequency, h is Planck's constant ($= 6.55 \times 10^{-27}$ erg sec.), E_1 and E_2 are the energies of the molecule in the two states, respectively. The absorption of light is the reverse process, producing a change from a stationary state of lower energy to one of higher energy.

A single atom is believed to be made up of one minute, massive, positive nucleus and numerous electrons so that the different stationary states must correspond to different configurations of the electrons. A discussion of the quantum rules according to which these stationary states are determined is beyond the purpose of this article. Each line of an emission spectrum, therefore, is produced by one of the many possible changes of the atom from a higher to a lower stationary state. Likewise, the absorption lines correspond to changes from states of low energy to ones of higher energy. The absorption line spectrum is, however, always much simpler than the emission line spectrum because at ordinary temperatures the vast preponderance of the atoms exists only in the stationary state of lowest energy, the normal state, and consequently can absorb light of only those frequencies which correspond to transitions from that state to those of higher energy.

The atom which has absorbed light now has a different electronic configuration and is, from one point of view, a new chemical substance, of high energy constant. If the light absorbed is in the visible region, the energy per excited atom is 2 or 3 volts, roughly equivalent to 50,000-75,000 gram calories

per gram mol (one volt of energy is the kinetic energy of an electron which has fallen through a potential drop of one volt. One volt per atom equals 23.0 kg. cal. per gm. mol.) The atom in this excited state may do one of several things. It may simply reradiate light of the frequency of that absorbed, it may radiate light of a lower frequency by a transition to an intermediate state, or it may give up its energy without radiating upon collision with another atom or molecule. It has been found by a variety of methods that an atom remains in one of these excited states into which it is put by absorption of radiation an average time of the order of 10^{-8} seconds.¹ If the excited atom is in a rarefied gas it will reradiate its energy before making a collision, so that such gases usually show some sort of a fluorescence spectrum. There are, however, for some atoms, a few stationary states in which the atom can remain an indefinitely long time without radiating any of its energy of excitation. This happens when there is a stationary state of greater energy than the normal one, but of such a sort that there is no possible transition from it to a lower state with the emission of radiation, or *vice-versa*. For instance, the excited state of a mercury atom of lowest energy which can be reached by the absorption of light is the 2^3P_1 state ($2P_2$ in the old notation) into which the atom is changed by absorption of light of a wave-length of 2537 Å. U. A small fraction of a volt below this is the 2^3P_0 state from which the atom can change to various higher states by the absorption of radiation; but, once in it, can not revert to the normal state by radiating, neither can it be brought to this state from the normal one by the absorption of radiation. In this and other such cases, these so-called metastable states can be reached, however, by transitions from states of still higher energy. It has been shown by Dorgelo² that in pure neon at low temperatures atoms will remain in 16.6 volt excited stationary states for at least $1/10$ of a second, as indicated by the absorption of light by atoms in these excited states. A slight trace of impurity cuts this life down to a time too small to measure.

This disappearance of the metastable excited atoms and the quenching of the fluorescence of a gas with increasing pressure or admixture of other gases show that the excited atoms can lose their energy by some other method, presumably upon collision with other atoms or molecules. Such processes were called "collisions of the second kind" by Klein and Rosseland³ who predicted them by a theoretical argument. They showed that if, when two atoms collide, part of their kinetic energy can be used to raise one of the atoms to an excited stationary state (a "collision of the first kind") the reverse process must also be a possible one. Various sorts of collisions of the second kind were experimentally investigated by Cario and Franck⁴ who showed that Hg atoms excited by the absorption of light of a wave-length of 2537 Å. U. can excite other atoms such as Tl and Na, which will emit their own spectrum, the excess energy appearing as kinetic energy. They also showed that the excited Hg atoms will produce a chemically activated form of hydrogen, presumably atomic hydrogen. All of the energy of excitation is not necessarily used up in the process occurring at the first collision. The atom may first be put into a metastable state, giving up a small amount of energy, and then remain there

until it finally makes a collision in a way favorable for it to give up all of its energy of excitation. Experiments of Donat⁵ and of Wood⁶ indicate that this is what happens to excited Hg atoms in mixtures with argon or nitrogen at pressures of the order of one-tenth to one atmosphere. Processes of this kind must be involved in the various photochemical reactions⁷ produced by illuminating mixtures of Hg vapor and other gases with 2537 light, many of which have been studied since Cario and Franck's original experiment. This type of photochemical reactions is, of course, a very special one for it is light of only an exceedingly narrow region of the spectrum which has any effect upon the mixture, viz., the very center of the 2537 line. Self reversal of this line removes all of the effective radiation if the mercury arc lamp used for a source is not sufficiently cooled.

Stuart⁸ has made a study of the quenching of the resonance fluorescence of Hg vapor produced by the admixture of various other gases. Different gases give vastly different quenching effects showing that the probability of a radiationless transfer of energy at collision depends upon the nature of the colliding molecules. It is of interest that the effectiveness of this quenching is so great for some gases that even if it is assumed that the probability of occurrence of a radiationless transition at collision is unity, it is necessary to ascribe a much larger effective radius to the excited Hg atom than the radius of the normal Hg atom as deduced in other ways. Similar experiments have been performed with Na vapor by Mannkopf⁹, who finds a different relative order of effectiveness for the different gases from that found by Stuart for Hg vapor.

In many cases the absorption lines can be arranged in series converging to a limit on the side of shorter wave-lengths. Beyond this limit there is a region of continuous absorption. The successive lines of a series, by Bohr's theory, have to do with transitions from the normal state to a set of states of higher energy, one electron becoming less and less tightly bound to the nucleus. The limit corresponds to complete removal of this electron, i.e., ionization. The region of continuous absorption beyond the limit corresponds to ionization of the atom and ejection of the electron with various amounts of kinetic energy, continuous because that kinetic energy can have any value. Such absorption by Na and K has been investigated by Harrison¹⁰ and the predicted photo-ionization has been studied by various workers.¹¹ The continuous absorption of X-rays is a similar phenomenon. Experiments with X-rays have shown¹² that the electrons have the expected velocity given by the equation

$$\frac{1}{2} m v^2 = h\nu - P$$

The spectra of molecules, both emission and absorption, are interpreted in the same way as those of atoms. The differences between them are to be attributed to the more complicated structure and resulting increase of the number of degrees of freedom of the molecules. For the molecules, as for the atoms, there are various electronic configurations but instead of each of these giving a single stationary state it is split up into a two-fold multiplicity because of the various possible energies of mutual vibration of the different nuclei of the molecule and the various possible energies of rotation of the molecule as a whole. All of these motions are quantized so that for a given

set of electron quantum numbers there are many possible vibration states and for each of these many rotation states. The number of stationary states of a molecule is therefore very great compared to that of an atom and the number of spectrum lines connected with transitions is correspondingly increased, giving rise to the complicated band spectra. For a complete treatment of this subject the reader is referred to the Bulletin of the National Research Council, No. 57, "Molecular Spectra in Gases."

This complication of the stationary states admits the possibility of transitions not possible for atoms. There are the rotation bands in the far infra-red region of the spectrum corresponding to changes of only the rotation of the molecule, and the vibration-rotation bands in the near infra-red corresponding to simultaneous changes of the vibration and rotation. The electronic bands are those which involve a change in the electronic quantum numbers and, therefore, correspond to a single line of an atomic spectrum but because of the complication of all the various possible simultaneous changes of the vibration and rotation the single line becomes a whole system of bands.

The excited molecule can, like the atom, reradiate part or all of its added energy to give a fluorescence spectrum. Such are the resonance spectra of I_2 , Na_2 , etc., studied by R. W. Wood¹³ and others. Collisions of the second kind presumably can occur and must be of great importance in the mechanism of photochemical reaction in which the absorbing substance is molecular, the exciting light being in the spectrum region of discontinuous band absorption. There is one possible type of collision which results in the dissociation of the excited molecule itself into component parts—a sort of auto-collision of the second kind. The energy of excitation of many molecules is considerably greater than the energy for dissociation and it seems quite probable that upon collision this excited molecule can give up its energy by dissociating itself. There is no very direct evidence for the occurrence of this process. Nor is much known about possible, molecular, metastable, excited, electronic states. There is evidence, however, that many electronic transitions of kinds which do not take place in atoms do occur in molecules so that the probability of the existence of these metastable excited states is much less.

Various band spectra have been analyzed and the electronic transitions discovered. In one case, that of the He_2 bands, there has been found a sequence of transitions converging to a limit according to the same law as do the lines of a series, and apparently for the same reason. Theoretically, at least, one might expect to be able to follow many such sequences to the limit of convergence and find a region of continuous absorption connected with ionization of the molecule. Such an absorption has not been found.

There are, however, regions of continuous absorption in the spectra of molecules which seem to be connected, not with ionization, but with dissociation of the absorbing molecules. They are continuous because of the continuity of the possible kinetic energies of the separated atoms. It is found that the energies of the excited states having the same electron quantum numbers are greater the greater the vibration quantum numbers, as one would expect, but that with increasing vibration quantum number the energy differ-

ences between these states become steadily less. (It is implied that molecules having zero rotational energy are being compared). The energies of these successive states can in several cases be represented by a very simple formula involving the vibration quantum number. It indicates that the energy difference between successive vibration states becomes zero for a finite vibration quantum number and a certain value of the energy. This is thought to be the energy at which the molecule dissociates into atoms. According to the quantum theory of the anharmonic oscillator the energy difference between successive vibration states is proportional to the frequency of vibration so that when this difference becomes zero so does the frequency, indicating that the binding force has become zero.

As an example, consider the absorption spectrum of iodine. Cold iodine vapor has a discontinuous band absorption in the red to green parts of the visible spectrum which merges into a region of continuous absorption beginning at about 4995 Å. U. and extending into the violet. The bands have been analyzed and are apparently connected with transitions from the single normal vibration state (actually multiple because of the various rotational energies) to various vibration states of one excited electronic configuration. The frequencies of these bands are related by a simple law which indicates that the frequency difference between them becomes zero at 4995 Å. U., the result of the convergence of these upper vibration levels. Dymond¹⁴ found that if iodine absorbed light of wave-length longer than this it would fluoresce but that if it absorbed light of a shorter wave-length in the region of continuous absorption there would be no fluorescence. In the first case the molecules were simply excited and could reradiate their energy but in the second case they were apparently actually dissociated.

Absorption of light of a wave-length of 4995 Å. U. will, therefore, produce dissociation of the molecule into two separate atoms having zero kinetic energy. The energy is 2.469 volts (volts $\times \lambda$ in Å. U. = 12345), whereas the experimental value for the heat of dissociation of I_2 is only 1.5 volts. The difference of 1.0 volts must be an energy of electronic excitation of at least one of the two atoms. Such an electronic energy would be expected since this optical dissociation is continuously connected with the band absorption which does involve an electronic change. On the other hand, when dissociation occurs the electronic energy must be that of one of the excited states of the atom. The spectrum of the iodine atom has not been analyzed, but, theoretically, there should be a low state near the normal one, the two forming a doublet P state. A recurring doublet difference between the frequencies of some of the strong lines of I in the Schumann region has been found.¹⁵ It presumably gives the energy of this next to the lowest state, the value being 0.937 volts. Subtracting this from the 2.469 volts energy for optical dissociation gives 1.532 volts as the heat of dissociation of iodine. This value is equivalent to 35.2 kg. cal. per mol. which is in satisfactory agreement with the direct experimental value of 34.5 kg. cal. per mol. Granting the theoretical interpretation of the spectra, the optical value is the more accurate. Kuhn¹⁶ has made

a similar study of Br_2 and Cl_2 and finds the same sort of relationships. The results are summarized in Table I.

TABLE I

λ of convergence	$h\nu_0$	$2^2P_2 - 2^2P_1$	D (spectroscopic) volts	kg cal	D (thermal)
I 4995	2.469V.	0.937	1.532	35.2	34.5
Br 5107	2.415	0.454	1.961	45.2	46.2
Cl 4785	2.577	0.109	2.468	56.9	57

One would expect that every set of vibration levels would converge in this way, the different sets being connected with different electronic states of the molecule and of the separated atoms. For substances of which the band spectra have been sufficiently analyzed and for which the various atomic states are known, it should be possible to get several independent determinations of this energy of dissociation. This has been done for one substance, hydrogen. Witmer,¹⁷ from the set of vibration states of which the normal state is the lowest found a heat of dissociation of 4.34 ± 0.01 volts. Dieke and Hopfield¹⁸ found in the far ultra-violet region of the spectrum a set of absorption bands and a region of continuous absorption as in iodine, continuous absorption beginning at 849.4 \AA . U. This limit gives 14.53 volts for the energy of dissociation of the H_2 molecule into one normal and one excited H atom. Assuming the energy of excitation of the H atom to be that of the state next above the normal, 10.15 volts, a value of 4.38 volts is obtained for the energy of dissociation. This agrees well enough with Witmer's value of 4.34 volts which involved a considerable extrapolation. 4.38 volts is equivalent to 100,900 kg. cal. per mol., in satisfactory agreement with the best direct experimental values. These ideas have been extended and applied to various other molecules by Birge and Sponer.¹⁹ The whole matter is discussed at length in Professor Birge's chapter in the report on molecular spectra in gases, referred to above.

Although it should be possible to apply these calculations in all cases, given a sufficiently complete analysis of a band spectrum, it does not necessarily follow that in all cases it is possible that normal molecules can be made to dissociate by the absorption of radiation, as the halogen molecules apparently actually do. The occurrence of such a dissociation means that there is a great probability of a large change of the vibration quantum number accompanying the electronic change. Franck²⁰ has pointed out that there is a connection between the change of the moment of inertia of the molecule in a transition and the magnitude of the most probable change of the vibration quantum number. The moments of inertia can be calculated from the energy differences between successive rotation states. In the spectra of substances like iodine, the moment of inertia of which is increased with the change to the higher electronic state, large changes of the vibration quantum number are the most probable, whereas in the spectrum of nitrogen of which the moment of inertia changes by a small amount, the most probable changes of the vi-

bration quantum number are the small ones. The increase of the moment of inertia means a corresponding increase of the separation between the nuclei in their position for equilibrium. It seems as if the electron configuration were changed from the normal one to the higher one instantaneously, leaving the nuclei practically the same distance apart. If this distance is then much less than the equilibrium distance for this excited state the molecule finds itself highly compressed and, being free to vibrate, does so with large amplitude. It may be that the energy of compression is greater than the energy necessary for complete separation of atoms when the nuclei are at rest in the equilibrium position. In this case the compressed molecule will expand, the nuclei passing through the equilibrium position with sufficient energy to separate completely with some kinetic energy left over. Whether this be the explanation or not, there is, nevertheless, the connection between a high probability of large change of the vibration quantum number and large change of the moment of inertia. The various other possible cases are discussed by Franck. Kuhn¹⁶ points out that I_2 , Br_2 and Cl_2 have, in the order given, a progressively greater weakening of the binding upon absorption as measured by the energy difference between successive vibration levels. The maximum adsorption by I_2 occurs just at the edge of the continuous region, that for Br_2 further into the continuous region, and that for Cl_2 well into it. There is, then, this sort of independent evidence for the primary optical dissociation of these halogen molecules by the absorption of light, which has often been postulated in the explanation of various photochemical reactions.

There is another type of process which may be of importance in photochemical reactions. It seems probable that in some cases a molecule in a quantized state may, instead of undergoing a transition to a lower state of high vibrational energy, change to a state where the atoms are completely separated, the remaining energy being radiated. A continuous emission spectrum would result in cases where this sort of process could occur. Blackett and Franck²¹ have advanced this as the best explanation for a certain continuous emission spectrum of H_2 which their experiments show to be the result of primary processes, i.e., independent of collisions with other molecules. Born and Franck²² have suggested the converse process to explain certain continuous absorption spectra such as the absorption by Hg vapor at high pressure on the long wave-length side of the 2537 line. Two atoms colliding with large kinetic energy form a temporary "quasi-molecule" which can absorb light to produce a definite quantized excited molecule, part of the energy being the kinetic energy of the colliding atoms, the rest being made up by the radiation. Such absorption may be of importance in photochemical reactions between gases at ordinary pressures.

The effectiveness of these atoms resulting from the dissociation of the molecule must depend to a certain extent upon the fact that in some cases they do not readily recombine to form molecules. This is in accord with Bohr's Correspondence Principle, in the case of highly symmetrical molecules such as I_2 or H_2 . Such highly symmetrical molecules when vibrating in the normal electronic state presumably have no vibrating electric moment. Classically,

they would neither emit nor absorb radiation so that the corresponding quantum radiation, the vibration-rotation bands, are missing. Such molecules can not be dissociated by absorption of radiation unless an electronic transition occurs so that the two atoms will not recombine with emission of radiation if both are in the normal state. Thus they do not combine except when there is some other body to take up the extra energy, as in a three body collision, or at the surface of a solid.

Practically all of the important theoretical and experimental work on band spectra has been done with diatomic molecules. Even they are sometimes rather hopelessly complicated so that it is not surprising that not much progress has been made in the study of spectra of still more complex molecules. There is no reason to doubt, however, that these more complicated molecules will behave in an analogous way.

In view of these various possible effects of the absorption of light it is no great wonder that Einstein's photochemical law is not accurately fulfilled by many reactions. Undoubtedly the primary process does follow the law, there being one excited system produced for each quantum absorbed, but even granting that none of the absorbed energy is re-emitted as fluorescent light, the subsequent course of the reaction will depend entirely upon the chemical properties of that excited system which may combine to give a small number of resultant molecules, or initiate a chain reaction, or act as a catalyst. The light merely serves to introduce an impurity, often of high energy content, into the system and the subsequent course of the reaction may be of almost any of the known types. The number of resultant molecules produced per quantum of light absorbed is, of course, an indication of the nature of the reaction subsequent to the absorption.

Since this article was written there have appeared numerous papers dealing with matters related to those discussed here. That NaI molecules are dissociated by the absorption of light of wave-length less than 2450\AA into normal I atoms and excited Na atoms, which then emit the P lines, has been shown by the experiments of Terenin,²³ of Kondratjew,²⁴ and of Hogness and Franck.²⁵ Franck, Kuhn and Rollefson²⁶ and Franck and Kuhn²⁷ have studied the absorption spectra of various alkali and silver halides. They discuss the theory of the optical dissociation of such heteropolar molecules and of the hydrogen halides, the absorption by which had been previously investigated by Tinge and Gerke,²⁸ and Bonhoeffer and Steiner.²⁹ That exceedingly dry chlorine has the same absorption spectrum as moist chlorine has been found by Kistiakowsky,³⁰ and by Kornfeld and Steiner,³¹ thus showing that the great influence of H_2O vapor upon the photochemical combination of H_2 and Cl_2 is one upon the reactions following the primary absorption. The author³² has recently found that iodine vapor illuminated by strong light from a carbon arc absorbs the light of the 1830.4 line of the iodine atom more strongly than when not so illuminated. This light should be absorbed by normal iodine atoms, so the experiment is taken to indicate the presence of the iodine atoms resulting from the optical dissociation.

QUANTUM PROCESSES IN PHOTOCHEMISTRY

BY HUGH S. TAYLOR

The modern theory of absorption and emission of radiation by quanta is at once both an amplification and limitation of the fundamental law of photochemistry formulated by Grotthuss and restated in its application to the hydrogen-chlorine reaction by Draper. According to this law only light which is absorbed by a chemical system is active in producing chemical change. Quantum theory amplifies this law by defining more particularly the absorption act. The progress which has been made in this definition is indicated in a preceding communication of this series by Turner.¹ In so far as the quantum theory of absorption sets a limit to the energy available in a single absorption act it also sets a limit to the nature of chemical change that can result from such absorption. Thus, for example, if the absorbing system be composed of a single type of diatomic molecules and the light energy absorbed per quantum is less than the energy of dissociation of such molecules, it follows that such dissociation cannot occur as the result of absorption of a single quantum. Whether such dissociation may occur when the energy of a quantum exceeds the dissociation energy has already been discussed in some of its bearings by Turner. The relationship laid down by quantum theory between the energy of a quantum and the frequency of the radiation absorbed is given by the equation

$$Q = N h \nu \quad (1)$$

where Q is expressed in calories per mol, N is the Avogadro constant ($=6.06 \times 10^{23}$), h is the Planck constant ($=6.554 \times 10^{-27}$), ν is the frequency ($=c/\lambda$ where c is the velocity of light and λ its wave length and equals $1.048 \times 10^{10}Q$).

During the past two decades, largely as a result of ideas first put forward by Stark² and made definite by Einstein,³ the relationship between absorbed light energy and chemical reaction produced has been intensively studied. The attempt has been made to show that a simple numerical relationship exists between the number of absorbed quanta and the number of molecules brought to reaction as a result of the light absorption. In the most definite form, sometimes known as the Einstein Law of the Photochemical Equivalent, an exact equivalence between absorbed quanta and reacting molecules was postulated. Abundant evidence is now available to show that this exact equivalence only holds in very exceptional circumstances and that, in the majority of photo-chemical reactions, the relationship obtained deviates from equivalence to an extent characteristic of the system in question. The deviation may be in both directions. Many systems show manyfold fewer reacting molecules than absorbed quanta. At the other extreme are reactions in which an enormous number of molecules react for every absorbed quantum. It might therefore be asked what advantage there could be in retaining the con-

cept of a relationship between quanta and reacting molecules. It is the aim of the present article to set forth considerations which bear upon this problem.

The Analogy between Electrochemical and Photochemical Processes. Since the time of Grotthuss, and especially in recent times by Bancroft⁴ and by Baur,⁵ an analogy between electrochemical and photochemical processes has been stressed. The modern theory of quanta applied to photochemical systems is very much more definite than any such process of analogy. For the idea that the action of light is analogous to that of a voltaic cell or that 'photolysis is a molecular electrolysis,' quantum theory substitutes a perfectly definite statement as to the actual stages in the whole process. It postulates that the absorbing constituent of the system is changed by absorption of light, from its normal energy state in the dark, to an energy-rich form, the magnitude of the energy increase per unit absorbent, atom or molecule, being exactly that of the quantum, $h\nu$, of absorbed radiation. When the absorbing system is atomic, the nature of the energy change can be stated in terms of the quantum theory of atomic structure. Thus, in the case of mercury, the absorption of light of wave length $\lambda = 2536.7 \text{ \AA}$, is accompanied by the passage of the atom from the normal atom state ($1S$) to the excited state known as the 2^3P_1 state. The energy associated with this change is given by Equation (1) as equivalent to 112000 calories per gram atom of mercury in the excited state. When the absorbing system is polyatomic the energy absorbed is not necessarily wholly associated with an electronic change, but may also be distributed between the vibrational and rotational degrees of freedom of the absorbent. The total increase of all such types of energy is, however, given by Equation 1.

The quantum theory of photochemical processes, therefore, accounts for the existence of photochemical reactions by the presence in the reaction system of an energy-rich species and also of species with which such energy-rich atoms or molecules may react. The nature of the chemical change brought about by the agency of the light will depend on the normal chemical reactivity of the system and on the available energy. It is thus possible for all such chemical reactions as occur in the dark to occur with one of the constituents activated by light. It is, however, possible that reactions may occur in the light, which occur only to a negligible extent in the dark, by reason of the larger units of activating energy involved. Thus, the chance that a molecule in a system at temperature T shall possess, thermally, a quantity of energy equal to 100,000 calories is given by the Boltzmann relationship

$$e^{-100000/RT}$$

which, for the ordinary temperature range, is very small. Molecules possessing such energy units are created every time a quantum of light of wave length approximately 2800 \AA is absorbed.

Depolarizers.—In stressing the analogy between photochemical and electrochemical processes Grotthuss and others have referred to the non-absorbing components of a photochemical system as depolarisers, and thus associated them with the electrochemical depolarisers which take part in electrode reactions on the discharge of ions. The quantum concept of photochemistry

applied to such components sees in them merely reacting constituents of the system which may or may not partake in the reaction process depending on the energy quantities available. In electrochemical systems the reactions are mainly oxidation and reduction since they are generally processes involving electron transfers. In photochemical systems not only do oxidation and reduction occur but every other type of chemical process is possible, halogenation, hydration, hydrolysis, polymerisation or condensation, depolymerisation. In general, the photo-reaction will not be associable with a transfer of electrons but will be associated with the definite utilisation of activating energy.

The approach to an examination of this energy utilisation may be made through consideration of thermal reactions. If we heat up a vessel containing hydrogen gas, there will be negligible chemical change in the system until extremely high temperatures are reached. That is because the chemical reaction which can occur in such a system is the dissociation of molecules into atoms.^(a) Now, in order to dissociate, a molecule must receive as activating energy at least the dissociation energy of 100,000 calories and this, as the Boltzmann expression above shows, is a seldom occurrence. Marked concentrations of atomic hydrogen are only obtained thermally above 2000°C. If, however, we introduce into the hydrogen gas some other reacting gas, reaction may occur long before such temperatures are reached. Thus, with iodine, reaction occurs at a few hundred degrees of temperature since, as is now known,⁶ the activating energy demanded of such a system is that the colliding molecules of hydrogen and iodine shall *jointly* possess some 40,000 calories. The iodine may be regarded as a thermal depolariser of the hydrogen. In the reverse reaction, the dissociation of hydrogen iodide, the substance may be thought of as its own depolariser. If unimolecularly dissociated, an activating energy not less than 68,000 calories (the dissociation energy) is required, whereas in the 'depolarized process,' the bimolecular reaction, only some 44,000 calories of activating energy are required by a colliding *pair* of molecules.⁶

Bromine acts in an entirely different manner as a 'depolariser' of hydrogen. On the basis of the experimental data of Bodenstein and Lind,⁷ Christiansen,⁸ Polanyi⁹ and Herzfeld¹⁰ all independently showed that bromine atoms were the immediate agents of 'depolarisation' as is indicated by the reaction scheme:

Oxygen is actually an extremely poor 'depolariser' for hydrogen gas. There is no experimental evidence that the homogeneous thermal gas reaction occurs to any reasonable extent when studied in closed systems.⁶ The bulk of the reaction is confined to the walls of the containing vessel.

Excluding the possible formation of polymers H₃, H₄, etc.

This varying reactivity of systems under the influence of thermal activation is exactly paralleled by photochemical systems. As recorded by Bancroft in a following paper, copper sulphate solutions are stable of themselves in light, but are readily reducible when white phosphorus is present in the system. Potassium permanganate solutions show a certain degree of instability under suitable illumination but this instability is enormously increased by the addition of sodium oxalate.¹¹ There does not, however, appear to be any essential point of difference between this and the thermal hydrogen and hydrogen-iodine systems just discussed. What is plain is that the reactivity of normal thermal systems of potassium permanganate and sodium oxalate is less frequent than the reactivity of photochemically activated permanganate with sodium oxalate. Such systems are, however, quite complex and it is desirable first to exemplify the quantum concept of photochemical reaction with much simpler systems, returning later to the more complex.

Hydrogen Iodide.—The simplest reaction system for which the most comprehensive data are available is hydrogen iodide. In this system the photodecomposition is unimolecular, indicating that single molecules only are involved in the decomposition process or, in the older mode of expression, the molecules do not act themselves as 'depolarisers' for the activated molecules. The reaction is proportional to the absorbed light energy over a wide variation in the state of the reactant. Thus, Warburg demonstrated this with gaseous pressures varying between 80 and 350 mm.¹² Bodenstein and Lieneweg¹³ extended this observation to liquid hydrogen iodide and quite recently Lewis¹⁴ has reached the same conclusion with gas pressures as low as 0.1 mm. Temperature has no influence on this ratio of absorbed energy to reaction rate. Warburg studied the decomposition with monochromatic radiation of wave lengths $\lambda = 2070, 2530$ and 2820 \AA . These measurements yielded results which are decisive from the standpoint of quantum theory. If we express the results obtained in terms of the number of gram atoms of iodine produced per gram calorie of light energy employed the following values are obtained:

λ	= 2070	2530	2820
Mol. I. $\times 10^5$	= 1.44	1.85	2.09

These results show that, *per gram calorie* of light energy, the extreme ultra-violet is *less* efficient than the longer wave length light. This surprising result, completely inexplicable without quantum theory, becomes, however, immediately understandable, when the quantum relationship is introduced. The calculation then shows that, at each wave length, the number of molecules decomposed per quantum of absorbed energy is 2.0 with a maximum deviation in all of the experiments of not more than 5 per cent, a deviation well within the experimental error. This ratio is also obtained by Bodenstein and Lieneweg for liquid hydrogen iodide at room temperature, for the gas at 150–175°C and by Lewis for the gas at 0.1 mm. pressure. These several results, as well as similar studies with hydrogen bromide, exhibit strikingly, therefore, that the relation between light energy absorbed and chemical reaction produced is a *quantum* relationship.

The quantum absorbed by a hydrogen iodide molecule secures its decomposition. Physical evidence by Tingey and Gerke¹⁵ and by Bonhoeffer and Steiner¹⁶ support this conclusion. But direct experimental evidence by Lewis,¹⁴ showing the independence of the quantum yield of molecular collisions, is decisive that the process of decomposition does not involve a simultaneous reaction of two hydrogen iodide molecules. The measurements already discussed indicate that the photochemical yield corresponds to two molecules of hydrogen iodide decomposed per quantum. It is evident therefore that the primary photo-decomposition must be followed by a series of 'dark' reactions which raise the yield to twice that of the molecules activated by absorption of a quantum. These supervening reactions are *not photo-reactions*. They are purely thermal reactions possible in the given system whether produced initially by photo-action or other means. Their effect is to raise the yield beyond that anticipated upon the basis of absorbed quanta. They offer a fruitful yield for the speculative chemist and have led accordingly to further experimental effort. In the hydrogen iodide case, the simplest of such suggestions which agrees with the experimental facts is that, after the true photochemical reaction,

$$\text{HI} + h\nu = \text{H} + \text{I} \quad (1)$$

the following sequence of reactions occurs:

Bonhoeffer¹⁷ has demonstrated that reaction (2) actually occurs as a purely thermal reaction at ordinary temperatures.

The Hydrogen-Bromine Combination.—When light of a wave length of 5107 Å or less is absorbed by moist bromine, the physical evidence now available shows that the molecule is dissociated into one excited atom and one normal atom. The energy corresponding to a wave length of 5107 Å is approximately 55,700 calories of which 45,200 calories is the energy of dissociation and the residual 10,500 calories is the energy of excitation of the bromine atom.¹ Shorter wave length light corresponding to larger units of energy would produce the same dissociation and the same excited atom, the excess energy being distributed, however, between the two as kinetic energy. It is well known, also, that all attempts to measure directly the concentration of bromine atoms in illuminated bromine vapor have failed to show any marked concentration. It therefore follows that, equating the light energy absorbed to atoms present in the illuminated system would give a ratio in which many millions of absorbed quanta correspond to unit dissociation of bromine. This is not in disagreement with the physical evidence. It only means that the reverse combination of bromine atoms occurs rapidly and that the measurement of atom concentration would only give a stationary state concentration under the given illumination and dependent upon this latter.

If we introduce hydrogen, as an acceptor (or 'depolariser') for bromine atoms produced, we find that the efficiency of the acceptor is dependent on the temperature of the system. It increases with increasing temperature. This means that the thermal processes which succeed the initial photo-process

are dependent upon temperature. Measurements of the quantum yield over such a temperature range will obviously show a remarkable variation. It has been estimated that, at room temperature, more than 100 quanta are absorbed per unit of hydrogen bromide formed. This ratio will also obviously decrease with temperature. At some one temperature it will be unity. Above this temperature it will be greater than unity. This in no way invalidates the physical evidence that one quantum of light energy produces one excited and one normal atom. It only means that the succeeding thermal processes result, with increasing temperature, in increasing production of hydrogen bromide and decreasing recombination to form molecular bromine. In the view of Christiansen, Herzfeld and Polanyi, the following sequence of reactions occurs: firstly, the light reaction is,

This is then followed by the following purely thermal processes:

Every one of these reactions is known to occur thermally. The investigations of Bodenstein and Lütkemeyer¹⁸ indicated that it is reaction (2) which is temperature-sensitive. The reaction only occurs thermally when the bromine atom and hydrogen molecule together possess an activation energy of about 17,000 calories. Reaction (4) accounts for the inhibiting action of hydrogen bromide. It is not possible here to enter into the extraordinarily interesting correlation by Bodenstein, of his thermal study with Lind⁷ on the formation of hydrogen bromide with that of Bodenstein and Lütkemeyer on the photo-process. It is sufficient if it has been indicated that the evidence from the purely physical side concerning the light-absorption process and its resulting bromine-atom formation supplies a reaction system with which, by purely thermal processes, the known facts of the photo-reaction are completely interpretable.

The Hydrogen-Chlorine Combination.—The same mode of interpretation is applicable to the historical hydrogen-chlorine reaction. The absorption by moist chlorine of light of wave length shorter than $\lambda = 4785 \text{ \AA}$ results in the production of a normal chlorine atom and an excited atom with an energy of excitation corresponding to some 2500 calories. With hydrogen present in the illuminated system, reactions similar to those occurring in the hydrogen-bromine system are possible. Among others we may have:

The essential difference between this and the bromine reaction is that, at room temperatures and upwards, Reaction (1) of the above sequence does not require any activating energy. The thermal reactions are not temperature-

sensitive. This conclusion is in accord with the thermal data, for, in Reaction (1) above, the process involves practically zero heat of reaction whereas the corresponding reaction between bromine atom and hydrogen molecule is endothermic to the extent of 17,000 calories and thus requires activation energy of similar amount. Why the hydrogen chloride does not inhibit the reaction in contradistinction to the action of hydrogen bromide is also explainable by the same set of facts as well as by the direct observation of Bonhoeffer¹⁷ that hydrogen atoms led into hydrogen chloride produce a marked thermal effect, but, the product is only hydrogen and hydrogen chloride without any final production of chlorine.

The extraordinary photochemical yield in the hydrogen-chlorine reaction (ca. 10^6 molecules per quantum) is therefore to be attributed to the facility with which a sequence of thermal reactions can follow the setting up of a reaction system containing atomic chlorine by the quantised process of light absorption.

Photo-sensitised Processes

The same attitude may be adopted towards photo-sensitised processes and, in such cases also, there is enough experimental evidence in simple cases to justify the procedure. The photosensitised processes differ from the photochemical processes in that the light-absorbing constituent is not a reactant in the chemical reaction occurring.

Excited Mercury as Sensitiser.—Undoubtedly the simplest of the photo-sensitised reaction processes are those involving excited mercury and hydrogen. For, in these cases, the light quanta involved are monochromatic, of exactly known energy content, producing physical and chemical effects the steps in which have been definitely ascertained. The normal mercury atom absorbs a quantum of mercury resonance radiation corresponding to the wave length 2536 Å and is thereby raised to the 2^3P_1 state, in which it possesses energy equivalent to 112,000 calories of energy. In the absence of foreign gases this energy is re-emitted as fluorescent radiation of the same wave length. With foreign gases present it may lose this energy by collision with the gas molecules without any radiation. If hydrogen be present, the energy transfer results in a photosensitised process, the conversion of molecular into atomic hydrogen with the absorption of 100,000 calories of dissociation energy, the excess 12,000 calories being distributed among the resultants (Hg, 2H) as kinetic energy. The presence of atomic hydrogen may be demonstrated by the 'clean-up' effect,¹⁹ by physical means such as the thermal conductivity of the illuminated system²⁰ or by the chemical reactivity of the atomic hydrogen.²¹

Were the experiment possible, the ratio between the number of quanta absorbed by the mercury atoms and the number of hydrogen atoms produced by subsequent collision might be ascertained. This would be the photochemical yield of the process. We know it would depend on the hydrogen pressure, since the extinction of the fluorescence is dependent on this pressure and increases with increasing pressure. With sufficiently high hydrogen

pressures we can conclude that every excited mercury atom should lead to the production of two hydrogen atoms. Any attempt to ascertain the ratio of quanta absorbed to atoms produced either by the 'clean-up' effect or by means of thermal conductivity would certainly yield a result less than two atoms per quantum since either method would fail to correct for the thermal recombination of hydrogen atoms formed.

Attempts by chemical means to ascertain the number of atoms formed per quantum absorbed would be subject to the same limitations that the hydrogen-halogen photo-reactions, already discussed, suffer. The thermal processes possible would determine the yield obtained. This has already been demonstrated experimentally in a number of cases. Thus, if ethylene is introduced as the acceptor for atomic hydrogen, the following reactions are possible

and the yield in terms of saturated hydrocarbons formed will be determined by the length of such sequences. The same is true with oxygen as acceptor where hydrogen peroxide is produced and with carbon monoxide where formaldehyde and glyoxal²² are identified products, probably by such sequences as

In all these cases the yield is not determined by the light quanta absorbed but by the reactivity of the system produced by the absorption process.

The Photo-sensitised Decomposition of Ozone.—The decomposition of ozone may be photosensitised to visible light by introducing chlorine or bromine into the gas. In either case the initial light absorption process by the halogen molecule must yield one excited and one normal atom. But, the subsequent yield of decomposed ozone is quite different in the two cases. As Bonhoeffer²³ has shown, only two molecules of ozone are decomposed per pair of chlorine atoms produced, whereas as many as thirty ozone molecules decompose per pair of bromine atoms resulting from light absorption. The explanation of this difference must lie in the different reactivities of the chlorine atom-ozone system and the bromine atom-ozone system. No one has yet indicated what these differences are or attempted other methods than photochemical of studying them. It is possible that some progress might be made in this regard by a study of the effect of temperature on the photo-sensitised processes.

The Stationary State

Several examples have already been discussed in which the absorption of light by a reactant results in the displacement of the system from its normal 'dark' equilibrium. The physical evidence indicates that in both illuminated

chlorine and bromine there exists a greater concentration of atoms than is present in the unilluminated system at the same temperature. The penetrating analysis of the hydrogen-bromine combination by Bodenstein and Lütke Meyer¹⁸ permitted a calculation of the respective 'dark' and 'illuminated' bromine atom concentrations at 218°C. The results showed that, for the intensity employed, approximately 300 times the concentration of atoms was present in the illuminated system. The stationary concentration was determined in part by the recombination of atoms to form molecules and, on the assumption that each quantum absorbed yielded two atoms, only about 0.0013 of all atomic collisions led to the formation of molecules. Had the quantum efficiency been calculated from the stationary state concentration the efficiency of the absorbed quanta would have been negligibly small.

There are a number of other reactions in which it is experimentally possible to determine the rate of the photo-reaction resulting in the displacement of equilibrium, independently of the dark reactions occurring simultaneously. These include the decomposition of nitrosyl chloride, the equilibrium, $\text{Fe}^{\cdot\cdot} - \text{Fe}^{\cdot\cdot\cdot}$, $\text{I}_2 - \text{I}^{\cdot}$, the polymerization of anthracene and substituted anthracenes. It is not possible to detail these in the scope of this article. One must suffice as an example.

The Equilibrium $\text{Fe}^{\cdot\cdot} - \text{Fe}^{\cdot\cdot\cdot}$, $\text{I}_2 - \text{I}^{\cdot}$.—Rideal and Williams²⁴ discovered that the rate of reaction in the initial stages of illumination of the thermal equilibrium solution, when the dark reactions compensate each other, provided a means of dissociating the photo-process from the thermal processes. In this way they were able to show that one molecule of iodine reacted per absorbed light quantum (5790 Å). Kistiakowsky²⁵ showed that this was true also of the light of wave lengths 5460 Å, 4360 Å and 3660 Å. In each case the relation was one molecule of iodine reacting per absorbed quantum. This situation is entirely analogous to that discussed in the case of hydrogen iodide. Without quantum theory, one has to explain why 78,500 calories of light energy of wave length 3660 Å is only as efficient as 43,850 calories of the longer wave length 5790 Å. Immediately the quantum concept is introduced this difficulty entirely disappears. There is an exact relation between the quantum absorbed and the activated molecules, and the method of study in this case eliminates the complicating thermal reactions which would mask the relation.

Inhibition

The necessity of distinguishing between the absorption act with its immediate chemical consequence and the chemical, purely thermal, reactions which succeed it, is nowhere more evident than in photo-reactions which show the phenomenon of inhibition. The classical example of inhibition in a photo-reaction process is the influence of oxygen on the yield of hydrogen chloride in the hydrogen-chlorine combination. We have recorded above that a large number of thermal reactions may succeed the original absorption act in this case and produce yields of the order of $10^5 - 10^6$ molecules of hydrogen chloride per quantum of absorbed light. Oxygen reduces the yield to an extent roughly proportional to its concentration so that hydrogen-chlorine mixtures

containing one per cent of oxygen are only feebly sensitive to illuminations which would produce explosions in the oxygen-free gas. The role of the oxygen in the process is still under discussion and no completely satisfactory conclusion has yet been reached. From the small concentration of oxygen required it is evident that the effect of the oxygen is exerted either on the atomic chlorine produced by the absorption act or on the thermal reactions subsequently produced.

The phenomenon of inhibition is not, however, confined to those photo-reactions for the explanation of which the reactivity of atomic species may be invoked. Thus, the photo-decomposition of aqueous hydrogen peroxide²⁶ and numerous examples of auto-oxidation such as those of benzaldehyde and of aqueous sodium sulphite solutions all show the phenomenon. It has now been shown by Bäckström²⁷ for all the auto-oxidations thus far investigated that the yield of oxidation product is many thousand-fold that to be anticipated on the basis of equivalence between molecules oxidised and quanta absorbed, thus confirming a prediction of Christiansen.²⁸ In the case of benzaldehyde the yield is approximately 10,000 molecules per quantum. With sodium sulphite the ratio rises to 50,000 molecules per quantum, an extremely striking result when it is remembered that this occurs in aqueous solution where there are more than 55 molecules of water for every molecule of sulphite (i.e., less than 1 Molar Sulphite solution). It is evident that there must follow the initial absorption act a whole series of thermal reactions producing sulphite oxidation. This agrees with the fact that even the purely thermal oxidation of benzaldehyde and sodium sulphite are also sensitive to inhibitors. The mechanism of the action of the inhibitor is only in the initial stages of study but unpublished results now available in Princeton indicate an intimate relationship between the amount of sulphite oxidised and the amount of inhibitor oxidised. The sulphite oxidised is inversely proportional to the concentration of inhibitor. The inhibitor oxidised is, however, *constant* over a very wide concentration range and with various alcohols as inhibitors, even though the inhibitor efficiency varies markedly. There is evidence that the amount of inhibitor oxidised is of the order of $1/5000$ of the sulphite which would have been oxidised had the inhibitor not been present. This evidence points overwhelmingly to the conclusion that, in the reaction without inhibitor, the initial photo-process is succeeded by a large number of thermal reactions which can be stopped by causing the energy-rich reaction products of the auto-oxidation process to oxidise the inhibitor. The stages of the auto-oxidation process have been studied in detail by Backstrom. On this basis, the phenomenon of inhibition becomes a special case of the well-known phenomenon of induced oxidation.

In the case of hydrogen peroxide solutions, the mechanism of the thermal processes have not been elucidated in detail. The extent of decomposition yield in the photo-process and the inhibitions of the purely thermal decomposition point, however, to the existence of thermal chain reactions.

Complex Photo-processes

We have seen that even in the relatively simple reaction systems already discussed there are still problems which have not yet received their final solution. It has been shown, however, that the method of approach here developed, of distinguishing between, on the one hand, the initial absorption act and its immediate chemical consequences and, on the other hand, the thermal reactions possible in a system thus photochemically produced, leads to an understandable interpretation of the total process. With more complex systems the difficulties increase since the factors to be controlled increase. Nevertheless, it can be shown, with one or two examples from these more complex processes, that the same guiding principles hold.

Oxidation of Quinine.—The classical researches of Luther and Forbes²⁹ on the photo-oxidation of quinine in presence of chromic acid are of use in this regard. In absence of chromic acid the light absorbed by quinine is re-emitted as fluorescence radiation. No photochemical reaction occurs. With small amounts of chromic acid present, a portion of the energy absorbed by the quinine is consumed in producing fluorescence and the residue in promoting reaction between active quinine molecules and chromic acid. In such cases it follows that the absorbed quanta are considerably in excess of the reacting molecules. With increase in chromic acid concentration, the probability of a quinine molecule losing an absorbed quantum as fluorescent radiation decreases and, hence, at a given acid concentration and beyond, a state of affairs obtains in which reaction with chromic acid follows immediately upon the absorption act. In such case there will be an equivalence between quinine molecules oxidised and quanta absorbed by quinine. There is, however, a complicating factor in that such a relation does not exist between reaction and total light absorbed since chromic acid absorbs but is not thereby converted into a reactive species. One further consequence of this also follows. In large excess of chromic acid, where the light is practically screened from the quinine, the photochemical yield would fall again from unity to practically zero.

Reduction of Fehling's Solution.—Another factor which influences the yield in processes initiated by light may be illustrated by the case of Fehling's solution. Byk³⁰ showed that the photo-decomposition of the solution itself was secured by light of frequencies in the ultraviolet absorbed by the cupri-complex present. No decomposition occurs if the solution is illuminated by the blue light of the visible absorption band. The system under these conditions is entirely analogous to the quinine system in absence of chromic acid. The absorbed radiations are transformed into radiation of other wave lengths (or otherwise dissipated). If, however, as Leighton³¹ showed, hydroquinone be introduced into such solutions illuminated by red light, reaction occurs and reduction takes place. The hydroquinone plays the part of the chromic acid in the quinine reaction. With increase in its concentration the photo-yield may be expected to rise from zero to unity as in the quinine case also.

Other complex systems will doubtless yield to patient and intelligent investigation; without this latter no progress can be expected.

Einstein's Law of Photochemical Equivalence

We are now in a position to examine the law of photochemical equivalence enunciated by Einstein in 1912 in the light of the yield of fifteen years of experimental study. The examples discussed in the preceding, together with many others which might have been cited, all suggest that the coupling of the concept of quantised absorption with the idea of net photochemical yield has not been sustained by the experimental test. The idea of photochemical equivalence which the title of the law suggests has not been confirmed by this practical work. Indeed, in the case of some workers, this suggestion of equivalence has given rise to mistrust of the general idea of quantised absorption which is basic to all these modern studies of photochemical processes and is demanded by physical theory.

It would therefore seem desirable to attempt a generalisation of the facts concerning the mechanism of the photochemical process which, while avoiding the difficulties inherent in the acceptance of the Law of Photochemical Equivalence as originally formulated would embody the elements of this law which have found support from its study. For this purpose it seems necessary first to avoid entirely the name which has become usual in reference to this matter, since equivalence has been demonstrated only in exceptional cases rather than as a general rule.

The situation may be met by means of two laws of photochemistry. The First Law of Photochemistry would be the Grotthuss-Draper Absorption Law, embodied in the statement that: Only light that is absorbed is effective in producing chemical change. This would be followed by the *Second Law of Photochemistry* which might thus be expressed:

The absorption of light is a quantum process involving one quantum per absorbing molecule (or atom). The photochemical yield is determined by the thermal reactions of the system produced by the light absorption.

Of this second law, the quantum concept of absorption is Einstein's contribution to the progress of photochemistry. The second half is a generalisation from the experiments of numerous workers who, in testing Einstein's original ideas, have added enormously to the quantitative knowledge of mechanism in photochemical processes and demonstrated the factors which determine the yield from a given illuminated system.

THE DISPLACEMENT OF EQUILIBRIUM BY LIGHT

BY WILDER D. BANCROFT

Before we can discuss profitably the displacement of equilibrium by light, it is necessary to be clear as to the general principles underlying the chemical action of light. In 1818 Grotthuss formulated the law that only that light which is absorbed by a substance can cause chemical change. This law was subsequently rediscovered by Draper and is often referred to as Draper's law. So far as we know, there are no exceptions to this law. A striking illustration of it is the behavior of a green alcoholic solution of chlorophyll in presence of air when exposed to magnesium light for half an hour behind a screen of potassium bichromate or one of ammoniacal copper sulphate. The color bleaches in the first case and not in the second. Herschel has studied cases where infra-red light causes chemical change.

While all light which is absorbed tends to produce a chemical change, all rays are not equally effective. It is well known that the ordinary photographic plate is much more sensitive to blue and violet light than it is to red and yellow. For this reason we get practically no action when photographic paper is exposed to magnesium light behind a solution of potassium bichromate and marked blackening when the light is transmitted through a solution of ammoniacal copper sulphate. Patent blue and Fehling's solution can be decomposed by light corresponding to the absorption in the ultra-violet but are apparently insensitive under ordinary conditions to light corresponding to the band in the red and yellow. It is rather the fashion nowadays, to account for the alleged greater efficiency of the ultra-violet light by saying that the quantum, $h\nu$, is larger the higher the frequency or the shorter the wave-length, and that consequently the greater energy is more effective.¹ The difficulty with an explanation of this sort is that it is a general one and therefore must be true in all cases. There is some evidence that it is not true for chlorophyll and consequently it is safer, for the present, merely to say that the chemical efficiency of different rays absorbed by a given substance is not necessarily the same and that, in many cases, light of short wave-length is more effective than light of longer wave-length.

We get all degrees of sensitiveness to light. Under ordinary conditions copper sulphate solutions are absolutely stable in light. Certain other solutions are stable so far as permanent changes are concerned; but undergo some change because they fluoresce under the influence of light. Many solids phosphoresce when exposed to light, and the existence of the time factor is in itself evidence of some change in the substance, even though we may not be able at present to say definitely what that change is. Water is absolutely

¹ H. S. Taylor (preceding paper) says that with iodine the extreme ultra-violet is less effective per gram calorie of light absorbed than the longer wave-lengths because the gram-calorie is a smaller fraction of the quantum, the higher the frequency. He does not explain why Fehling's solution is less sensitive in the red and yellow than in the violet.

stable so far as the visible spectrum is concerned; but it can be decomposed to some extent by ultra-violet light. Alcohol is decomposed very slowly by ultra-violet light at ordinary temperatures and quite rapidly at higher temperatures.

A potassium bichromate solution is stable to light of the visible spectrum when pure; but decomposes in presence of suitable organic material. We get some blackening of silver salts even when practically pure and more when organic matter is present. Many dyes are bleached by light in presence of air. Light decomposes mercurous chloride even in the absence of air, and Eder's solution of mercuric chloride dissolved in ammonium oxalate solution is used for the measuring of light. A mixture of hydrogen and chlorine reacts under the influence of light which is absorbed by chlorine. Carbon monoxide and chlorine react to form phosgene, COCl_2 . Hydriodic acid gas is decomposed by light, blue light being especially effective. This should mean that hydriodic acid has an absorption band in the blue; but I have never seen any statement to that effect. The matter should be investigated because there is always a possibility of a sensitization directly or indirectly by iodine.

In the original paper by Grotthuss in 1818 he stated that the action of light is analogous to that of a voltaic cell. This has recently been put forward by Baur¹ without any reference to Grotthuss. "Photolysis is a molecular electrolysis." I discussed this view at some length fifteen years ago.²

"While the statement that light acts as a voltaic cell has proved to be an excellent working hypothesis for cases involving oxidation and reduction, its usefulness is not so striking in cases involving allotropic modifications or polymerization. It is true that Berthelot³ has shown that soluble sulphur can be obtained at the anode by electrolyzing a solution of hydrogen sulphide and that insoluble sulphur can be obtained at the cathode by electrolyzing a solution of sulphuric or sulphurous acid; but the light is acting on sulphur and not on hydrogen sulphide or sulphurous acid. This did not bother me seriously at one time; but I then expected to prepare dianthracene electrolytically.⁴ This has been tried and we have not been successful. As that was admittedly a crucial test, I am prepared to abide by the result. It is also not absolutely satisfactory to have to say, in the case of organic substances, that light produces the same decomposition products that we should get if we could electrolyze the substance in question. It is quite possible that these difficulties may be overcome and that somebody may prepare dianthracene electrolytically.

"There is another more serious objection to the Grotthuss generalization in its present form. The selective action of light is much more marked than the selective action of the current. We can take a solution containing cadmium and copper sulphates and we can precipitate metallic copper by regulating the voltage. We cannot, however, precipitate cadmium from that

⁴ Trans. Am. Electrochem. Soc., 13, 257 (1908).

solution before the copper, though we can do it if we change to a cyanide solution. Suppose that we have two dyes of different colors which are oxidized about equally readily. By changing the wave-length of the light we can cause one dye or the other to oxidize in the air. So far as I know the only analogy to this in electrochemistry is the reduction of nitrates and nitrites.¹ At a smooth platinum cathode nitrite is reduced more readily than nitrate while the reverse is true at a spongy copper cathode. One difference between light and the electric current is that the current is a single reagent except in so far as the specific nature of the electrode may make a difference, while light is a mixture of reagents. Light of one wave-length may act on one substance and light of another wave-length on another, or lights of different wave-lengths may cause the same substance to react in different ways. This is not covered by the Grotthuss formulation and it is therefore necessary to make a more general statement."

The only thing that I should care to add to this quotation is that light of different wave-lengths can apparently decompose alcohol in at least two different ways:

While it would probably be a relatively simple thing to arrange a cell which would cause hydrogen and acetaldehyde to react with the formation of alcohol, I do not at present see how one could do anything similar with water and ethylene.

In 1905 I gave a formulation for electrolysis² which I have since found helpful. "In the case of electrolysis the only specific action which we have to attribute to the current is that it tends to set free the anions at the anode and the cations at the cathode. What happens over and above that is a question of chemistry depending on the reaction velocity and equilibrium relations in each particular case."

Three years³ later I wrote with reference to light: "The chemical effect of the light is merely to eliminate, if possible, the substance absorbing the light. Whether that elimination takes place as a result of oxidation or of reduction is a matter which is quite independent of the light and which depends on the nature of the depolarizer. If the depolarizer is a sufficiently strong reducing agent, we get reduction by light. If the depolarizing agent is a sufficiently strong oxidizing agent, we get oxidation by light. If it is not sufficiently one or the other we get no action by light. A very good instance of the variable action of light is to be found in the case of mercurous chloride. In the presence of a sufficiently powerful reducing agent, light reduces mercurous chloride to metallic mercury. In the presence of a sufficiently powerful oxidizing agent, light oxidizes mercurous chloride to mercuric chloride. If there is no

¹ Müller and Spitzer: *Z. Electrochemie*, 11, 509 (1905).

² Bancroft: *Trans. Am. Electrochem. Soc.*, 8, 33 (1905).

³ Bancroft: *Trans. Am. Electrochem. Soc.*, 13, 246 (1908).

more suitable depolarizer, the mercurous chloride itself acts as a depolarizer and is changed to mercury and mercuric chloride."

In 1912 I proposed the following generalization¹ as an improvement on the two laws of Grotthuss: "All radiations which are absorbed by a substance tend to eliminate that substance. It is entirely a question of chemistry whether any reaction takes place or what the reaction products are."

Since people do not, even now, think and talk in terms of depolarizers, it will be wise to discuss them more in detail. We distinguish between chemical depolarizers or sensitizers and optical ones. The action of the chemical depolarizer is quite simple. If we take a ferric chloride solution and expose it to light, we might hope to get ferrous chloride and chlorine; but the two could not coexist and therefore would be formed only to a slight extent, if at all. If we take an alcoholic solution of ferric chloride, the chlorine can react with the alcohol. It therefore takes less energy to reduce or decompose ferric chloride in alcoholic solution. Actually, we do get a photochemical change under these conditions. Alcohol or gelatine will act as a depolarizer for bichromate solutions. Chlorophyll and many dyes can react with the oxygen of the air under the influence of light. If we took a more powerful oxidizing agent, we could get a bleaching in the dark. With a weaker oxidizing agent we should have to use a more intense light and might not get oxidation even then. In presence of oxalic acid as depolarizer² we can get tellurium, selenium, and sulphur photochemically from solutions of telluric, selenic, and sulphurous acids respectively. In presence of air ferrous sulphocyanate solutions are oxidized to ferric sulphocyanate under the influence of light.

We can reduce many dyes photochemically in presence of a suitable amount of sodium or calcium hydrosulphite and we can oxidize them photochemically in presence of hydrogen peroxide. It is quite obvious that, in general, addition of a reducing agent will increase the tendency of a dye to reduce under the action of light, while addition of an oxidizing agent will increase the tendency to photochemical oxidation.

In some cases there is the unexpected result that addition of certain reducing agents increases the sensitivity of certain dyes to photochemical oxidation in presence of air. Thus methylene blue is readily oxidized photochemically by air when in presence of anethol or sodium bisulphite, both of them reducing agents. Nobody has worked out the theory of this; but it seems probable that part of the oxygen goes to the anethol and part to the methylene blue.

Byk³ has shown that ultra-violet light of wave-lengths somewhere between $350\text{ }\mu\mu$ and $400\text{ }\mu\mu$ cause the precipitation of cuprous oxide from a specially prepared Fehling's solution, while no rays of the visible spectrum cause any decomposition. "If that is the case, the precipitation of cuprous oxide must be prevented by the use of a ray filter which cuts off the ultraviolet. As a

¹ Bancroft: Eighth Int. Congress Applied Chemistry, 20, 33 (1912).

² Benrath: Chem. Ztg., 39, 25 (1915).

³ Z. physik. Chem., 49, 659, 679 (1904).

matter of fact, a one percent solution of quinine sulphate acidified with a little sulphuric acid protects Fehling's solution from the action of the sun's rays. The active rays are therefore really in the ultra-violet. In addition to an upper limit of about $400\text{ }\mu\mu$ for the wave-length of the active light, we can also give a lower limit. According to Precht¹ a tartrazin solution absorbs chiefly the wave-lengths $495\mu\mu$ - $362.5\mu\mu$, but cuts down the rays as far as $352.5\mu\mu$. Since tartrazin protects Fehling's solution, the active wave-lengths must be above $350\mu\mu$ and there must be a maximum sensitiveness between $400\mu\mu$ and about $450\mu\mu$."

By adding a suitable amount of hydroquinine to Byk's Fehling solution, Leighton² obtained a solution which did not decompose in the dark but which was reduced by red light. Bennett³ has shown that it is possible to add to a copper sulphate solution a solution of white phosphorus of such strength that there was no reduction in any reasonable time in the dark whereas there was a reduction in the light to copper which then reacted with the excess of phosphorus to form copper phosphide. Since a copper sulphate solution is a typical case of a deeply colored one which is ordinarily absolutely stable to light, this experiment is satisfactory proof that light of any wave-length which is absorbed tends to eliminate that substance.

Henri and Wurmser⁴ have studied a case which may differ in principle from that of hydroquinone. They find that acetaldehyde shows strong absorption and strong chemical action for light of wave-length $277.5\mu\mu$, and strong absorption and weak chemical action for light of wave-length $220\mu\mu$. They account for this by assuming that the first absorption is due to the aldehyde group and the second to the methyl group. This matter should be studied more carefully.

It is well known that some lithopones (zinc sulphide and barium sulphate) blacken in the light and it was shown by O'Brien⁵ that this was due to the formation of metallic zinc adsorbed by barium sulphate. This work has been repeated on a larger scale by Job and Emschwiller,⁶ who used a phosphorescing zinc sulphide and isolated more zinc than O'Brien did.

The production of the latent image on the photographic plate used to worry people a good deal. From energy considerations Hurter and Driffeld believed⁷ that it was impossible for a weak light to set free any silver from silver bromide. "That any ordinary camera exposure is inadequate to produce a material decomposition of the silver bromide on the plate can be shown by other experiments and considerations. A standard candle consumes 120 grains or 7.77 grams of spermaceti per hour, or about 0.0021 grams per second. The energy evolved by the combustion of 0.0021 gram spermaceti

¹ Z. wiss. Phot., 1, 262 (1903).

³ J. Phys. Chem., 16, 782 (1912).

⁴ Compt. rend., 156, 230 (1913).

⁵ J. Phys. Chem., 19, 113 (1915).

⁶ Compt. rend., 177, 313 (1923).

⁷ Phot. J., 22, 149 (1898).

(1 gram = 10000 units of heat) is 21 gram-units (small calories). If the whole of this energy were produced in the form of chemically active light and evenly distributed over a sphere of one meter radius = 12,663 sq. cm., the amount

of energy per sq. cm. of surface would be $\frac{21 \times 100}{125,663} = 0.016$ gram-units of heat.

"While it is possible on a sensitive plate to produce a deposit of 26.5 milligrams of metallic silver per 100 sq. cm. area by an exposure of 10 C.M.S., the amount of energy received by this area, assuming the whole energy yielded by the candle to be taken into consideration, as in the above calculation is $10 \times 0.016 = 0.16$ units in ten seconds. Now the decomposition of silver bromide equivalent to 108 milligrams of silver is 5.6 units, so that the candle, even if the whole of its energy of combustion were active in decomposing silver bromide, could only decompose 2.9 percent of the amount which experiment shows can be actually rendered amenable to development. As a matter of fact, however, only a small fraction of the energy of the candle is transformed into radiant energy; and again, a very small fraction of the radiant energy constitutes ethereal waves of sufficiently short wave-length to affect silver bromide. It is thus rendered quite evident that the candle can only furnish an infinitesimal part of the energy necessary to produce 26.5 milligrams of metallic silver per 100 sq. cm. with an exposure of 10 C.M.S., and that the whole of this energy is, in all probability, provided by the developer.'

Hurter and Driffeld evidently believed in the all or none principle. Since the developer admittedly did something, it must do everything. These difficulties are very real if we assume reduction to silver sub-bromide and still more serious if the silver bromide is reduced to free metallic silver. They vanish entirely on the basis of the adsorption theory, because the difference in the energy content of the undecomposed and the decomposed silver bromide can theoretically be made as small as one pleases. Practically, the difference which can be detected depends upon the sensitiveness of the developer.

When opening the general discussion by the Faraday Society on "Photochemical Reactions in Liquids and Gases," Professor Allmand¹ said: "The application of the quantum theory to photochemistry dates in practice from the enunciation by Einstein in 1912 of the so-called 'photochemical equivalent law,' a law, which, stated in its baldest terms, says that, in a photochemical reaction, one quantum of active light is absorbed per molecule of absorbing and reacting substance which disappears. This simple and attractive relation, put forward with the authority of Einstein, has proved a great stimulus to research in a somewhat neglected field of chemistry, and a field, moreover, in which an *impasse* seemed to have been reached in respect of such matters as the primary mechanism of photochemical change, the significance of the part played by the absorbed light, and the whole question of the classification of photochemical reactions. In this sense then, the relation has proved itself a working hypothesis of great value."

¹ Trans. Faraday Soc., 20, 438 (1925).

Fortunately for my peace of mind it does not come within the scope of this report to discuss the general accuracy of the Einstein equation; but it has been rather a surprise and a grief to me to find so many people working hard over possible chain mechanisms before they are absolutely certain of the accuracy of their premises. Suppose we take a reaction which does not go in the light in the absence of a depolarizer and which goes in the dark in the presence of a sufficient concentration of the depolarizer. If we expose the system for a given length of time to a given intensity of light and vary the concentration of the depolarizer, what quantitative relations shall we find, for the case that the absorption of the effective light by the depolarizer is negligible? Shall we get one quantum per molecule as soon as a reaction occurs and will it stay constant until the reaction takes place or shall we get an increasing efficiency of light with increasing concentration of the depolarizer? I have never seen any account of such an experiment or any reference to such an experiment and yet such measurements should be made with a large number of reactions because they are absolutely fundamental and because the results are independent of any assumption as to the mechanism of the photochemical reaction.¹

We can now consider optical sensitizers,² which might be called depolarizers with marked absorption bands. In 1873 H. W. Vogel was studying the effect of the solar spectrum on silver chloride, bromide, and iodide films. In one of his experiments he used an English silver bromide dry plate which had been stained yellow with aniline red to prevent halation. This plate showed a second maximum of sensitiveness in the green. Further investigation showed that this second maximum of sensitiveness corresponded to an absorption band in the spectrum of a solution of aniline red and that the abnormal behavior of the plate disappeared if the dyestuff were extracted with alcohol. This showed a relation between the sensitiveness of a silver bromide plate for certain wave-lengths and the absorption band for one dye. Vogel proceeded to test the matter further.³

"I made experiments, now, to see whether other dyes behaved similarly and whether they made silver bromide sensitive for those rays which they absorbed. I first tried coralline. A dilute solution of the same shows in the spectroscope an absorption band, like that of aniline red, between D and E; *it absorbs the yellow and the yellowish-green light*. On the other hand blue passes to a considerable extent. If the sunlight passes through the coralline solution and then through a prism; green and yellow are missing from the resulting spectrum. There is a dark absorption band in the place where yellow and green are usually to be seen.

"I now dissolved coralline in alcohol and added it to my collodion emulsion so that the latter was dyed a deep red. From this collodion, silver bromide

¹ Since this was written H. S. Taylor (preceding paper) says that the number of moles decomposed per quantum will vary from zero to unity with increasing concentration of the depolarizer. Barring some new factor, the upper limit should be infinity and not unity.

² For additional details, see Bancroft: J. Phys. Chem., 12, 318 (1908).

³ H. W. Vogel: "Handbuch der Photographie," 4th Ed. 1, 204 (1890).

dry plates were prepared which were dyed distinctly red. When these were exposed to the spectrum, my prediction was fulfilled. *The plates were sensitive in the indigo, the sensitiveness decreasing in the direction of the clear blue and becoming very slight at F. From there on the sensitiveness increased, becoming nearly as marked in the yellow as it was in the indigo.* A means had thus been found of making silver bromide plates which should be acted on just as readily by the yellow, which had hitherto been considered a chemically inactive color, as by the indigo, which had previously been considered the spectrum color producing the greatest chemical effect.

"From these experiments I was justified in concluding that some other substance would increase the sensitiveness of silver bromide for the red provided that substance absorbed the red to a marked extent. Such a substance I found among the green aniline dyes. It absorbed the red rays pretty thoroughly between the lines D and C; at higher concentrations, the absorption extended beyond D. Yellow, green and blue passed through with practically no absorption. A collodion dyed with this green proved in fact to be sensitive to light down into the red.

"The sensitiveness decreased gradually from the indigo to the yellow and was almost nothing in the orange. From this point the sensitiveness increased becoming very marked in the red just where the absorption band occurred.

"From these experiments I feel justified in concluding with a good deal of certainty that we are able to make silver bromide sensitive to any desired color, or to increase its existing sensitiveness for certain colors. It is only necessary to add a substance which will promote the decomposition of silver bromide and which absorbs the rays in question, letting the others pass. *The aggravating difficulty in regard to the photographic ineffectiveness of certain colors appears to be a thing of the past.* . . .

"This conclusion met with little favor at first. Distinguished investigators, like Schultz-Sellack,¹ Monckhoven, Carey Lea² and Abney, tried to show that the author's results were wrong. In the British Journal of Photography for 1874, the discovery of the author was jeered at and made fun of.³ The Berlin Academy of Sciences, however, recognized the importance of these results and made a considerable grant to the author to enable him to carry on his investigations and to procure suitable spectrum apparatus.

"The reason for the protracted opposition to the author's results is partly due to the fact that very few people at that time were clear as to the connection between chemical action and absorption. Even in 1876 Abney assumed that those rays acted the most on a photographic plate which were transmitted the most completely. Also, there was a widespread ignorance in regard to absorption spectra. Then, too, the majority of those, who tried to duplicate the author's results, failed because they dyed the films too heavily

¹ Ber., 7, 386 (1874). As the text shows, there is absolutely no truth in the assumption recently advanced that it was Schultz-Sellack's investigations which caused the author to study the effect of dyes on collodion.

² Although Lea fought the author's results obstinately, he is now, curiously enough, spoken of as one who helped to develop color-sensitive photography.

³ Photogr. Mittheilungen, II, 100.

and exposed them for much too short a time. Finally the dyes available at that time were so impure that the silver baths or the collodion emulsion, as it was then prepared, soon became spoiled. As far as the introduction of the principle into commercial practice was concerned, the prospect seemed at first absolutely hopeless. The author himself only obtained one good plate to five bad ones."

There is no question nowadays about the existence of optical sensitization. Sensitizing dyes are used in all forms of panchromatic or orthochromatic plates and in many plates used for special purposes. In order to minimize the difficulties due to haze in aerial photography the Eastman Kodak Laboratory has perfected a dye which sensitizes so well that it is possible to take aerial photographs through a red screen with exposures as short as one one-hundredth of a second. The theory of the process has not kept pace with the empirical progress of the art.

There is no explanation at all for the behavior of the different silver halides, though Vogel obtained some facts. Silver chloride collodion dyed with naphthalene red "showed a sensitiveness which corresponded almost exactly to that of the human eye for blue and red. Further experiments established the surprising fact that many dyes, which worked admirably with silver bromide collodion, did not produce the same effect on silver chloride collodion. This is true for magenta, for instance. It makes silver bromide very sensitive to yellow, and affects silver chloride much less. Naphthalene red acts equally well with both salts. These dyes act also upon silver iodide but to a very much lesser extent."

Bothamley¹ has given a pretty fair summary of our knowledge in 1895. "Although large numbers of dyes have been examined since Dr. H. W. Vogel's discovery in 1873, very few exert any marked effect in making gelatino-bromide plates sensitive to the less refrangible rays of the spectrum. Only cyanin and the dyes of the eosin group (including the rhodamines), with perhaps malachite green, chrysoidine, and alizarin blue, can be said to exert any useful effect.

"The main points established by previous observers may be summarized as follows: (1) The dyes that act as sensitizers are readily affected by light when they are in contact with fabric, paper, etc.; (2) in order that a dye may act as a sensitizer it must have the power of entering into intimate union with silver bromide, forming a kind of 'lake'; (3) and it must show a strong absorption band for the particular rays for which it is to sensitize. Although these statements hold good for all the dyes that are known to act as sensitizers, it is important to observe that the converse is not necessarily true. Several dyes having all these properties show no appreciable sensitizing action.

"Experiments by Dr. E. Vogel on the rate of fading and the sensitizing action of the eosin dyes, led him to the conclusion that the order of sensitizing effect coincides with the order of fading when the dyes are exposed to light.

¹ British Association Reports, 1895, 661.

The order in which Vogel places the dyes does not, however, correspond with the order of fading as observed in dyed fabrics, and the experimental method that he used is open to criticism.

"The author's observations on the fading of the various sensitizers, when exposed to light in contact with gelatin, led him to the conclusion, that although all the sensitizers are readily affected by light, the order of sensitizing effect does not necessarily correspond with the order of fading, whether the dyes belong to the same chemical group or not.

"There are two chief hypotheses as to the mode in which the dyes act, namely: (1) the view held by Abney that the dye itself is oxidized by the action of light, the oxidation product remaining in contact with the silver bromide; and when the plate is treated with the developer, the latter and the oxidation product acting simultaneously on the silver bromide bring about its reduction; and (2) the view first definitely formulated by Eder, and endorsed by Vogel, namely, that the energy absorbed by the dyed silver bromide is partially used up in bringing about the chemical decomposition of the silver bromide, instead of being almost entirely converted into heat, as when absorbed by the dye alone.

"The author has found that the less refrangible rays will produce a photographic image on the sensitized gelatino-bromide plates, when they are immersed in powerfully reducing solutions, such as a mixture of sodium sulphite and pyrogallol. This holds good for cyanin, the eosin dyes, the rhodamines, and quinoline red, whether the sensitizer has been added to the emulsion or has been applied to the prepared plate in the form of a bath. It is, therefore, impossible to attribute the sensitizing effect to any intermediate oxidation of the dye.

"Experiments with various reagents such as potassium bromide, potassium dichromate, mercuric chloride, and dilute hydrogen peroxide seem to show that the chemical nature of the latent image produced by the less refrangible rays on the specially sensitized plates is precisely the same as that of the latent image produced by the more refrangible rays in the ordinary way.

"Further proof in the same direction is afforded by the fact that the effect of the sensitizers extends to the production of a visible effect by the prolonged action of light.

"The balance of evidence is therefore greatly in favor of the view that the dye absorbs the particular group of rays, and, in some way which is not at all clear, hands on the energy to the silver bromide, with which it is intimately associated, and which is thereby decomposed.

"For the present, for want of a better word, the phenomenon might be distinguished as *photo-catalysis*, and the sensitizer might be described as a *photo-catalytic* agent. As yet no connection can be traced between the chemical constitution and the general properties of a dye, and its sensitizing action."

With dyes that are bleached by light in the presence of air, it is the light which is absorbed by the dye in most cases which causes the bleaching. It is therefore probable, though not proved, that the optical sensitizers which are

not fast to light depolarize the silver bromide themselves or their decomposition products do. Of course it is necessary that these sensitizers shall dye silver bromide and it is possible, though also not proved, that the different behavior of the sensitizers with silver chloride and silver bromide in some cases is due to a difference in the adsorption of some dyes by the two halides.

In the bleach-out process we considered anethol as a special case of a chemical sensitizer for certain dyes in presence of air. If the anethol is oxidized, as we feel sure it must be, it would be legitimate to consider these same dyes as optical sensitizers for anethol in presence of air. Wager¹ has studied what seems to be a slightly different case, in which certain dyes act as optical sensitizers for the oxidation of iodide. "If strips of paper are soaked in solutions of the following dyes—methyl violet, methyl green, eosin, fuchsin, and fluorescein—and are then exposed to light and afterwards treated with a ten percent solution of potassium iodide, the iodine is liberated and the starch contained in the paper is colored blue or reddish blue, a strong reaction being obtained in all cases. Cyanin, on the other hand, although readily bleached by the light, does not give this reaction.

"Experiments made with narrow glass tubes lined with a thin layer of methyl violet and eosin show, on exposure to light, that, during the process of bleaching, oxygen is used up, but this is not the case with cyanin, which becomes completely bleached without any appreciable rise of water in the tube. In the case of methyl green and eosin, the absorption does not take place as rapidly and is not so pronounced as in the case of chlorophyll."

The cases studied by Wager are relatively simple because the reaction can be made to take place in two stages. It is quite certain that we have formed an oxidation product of the dye which oxidizes iodide to iodine. It is therefore not a splitting of oxygen, one half going to the dye and the other half to the iodide, though it would have looked like that if an amount of iodide equivalent to the dye had been added to the paper before the dye was bleached.

Of recent years some cases of optical sensitization have been studied which apparently cannot be included under the head of chemical depolarizers. A typical case is the effect of chlorine on the photochemical decomposition of ozone. Griffith and McKeown² point out that "the decomposition of ozone may be photosensitized by addition of chlorine, as shown by Weigert³ and recently investigated by Bonhöffer.⁴ The effective light in this case (in the region $\lambda = 416 \mu\mu$) is strongly absorbed by chlorine, but practically not at all by ozone. The reaction is zero-molecular with respect to ozone, and Bonhöffer has found that each quantum absorbed by the chlorine results in the decomposition of two molecules of ozone. Bromine also acts as a sensitizer, but here about thirty molecules of ozone are decomposed per quantum absorbed by the bromine."

¹ Proc. Roy. Soc., **87B**, 397 (1914).

² Trans. Faraday Soc., **20**, 598 (1925).

³ Z. Elektrochemie, **14**, 591 (1908).

⁴ Z. Physik, **13**, 94 (1923).

Bodenstein¹ has discussed this case more in detail. "We are familiar with several so-called sensitised reactions. These are reactions in the course of which a substance absorbs light without itself undergoing any change, while another substance, which is also present, undergoes a chemical reaction at the expense of the energy absorbed by the former. The oldest photochemical process, the foundation of our very existence, the growth of plants, is one of these "sensitised" reactions. A number of more transparent examples are now known, mainly as the result of Weigert's investigations.²

"The most thoroughly investigated of these is probably the decomposition of ozone sensitised by chlorine. Here chlorine absorbs the light without reacting itself, and for each quantum of this light two molecules of ozone are decomposed.³ This provides an extraordinarily simple kinetic equation:

$$-dO_3/dt = k.$$

"The decomposition of ozone, when plotted, shows a straight line which suddenly turns off horizontally the moment the ozone is used up.

"This process can of course only be explained by supposing that the chlorine molecule communicates its surplus energy to the ozone molecule, thereby causing its decomposition. It is of no concern how the communication of energy takes place. But the fact that the yield is quite independent of the ozone concentration shows that the chlorine molecule with its surplus energy collides often when the ozone concentration is small and less often when it is great, before it finds an ozone molecule to decompose. (The collisions may take place with chlorine itself or with oxygen.) This means either that it cannot communicate its energy at all except to an ozone molecule or that it can possibly communicate it to another chlorine molecule, which thus simply takes its place."

"A particularly interesting case of this communication of energy is shown by the dissociation of ozone. This process has been the subject of extensive experiments⁴ with ultra-violet as well as red light. The results were not very transparent. Now Dr. Kistiakowski has taken up the investigation again in my laboratory and has succeeded in showing that the contradictory results given in the older papers are due, to a very great extent, to an unsuitable interpretation of the experiments. His observations showed that the ozone molecules activated by the absorption of light must be divided into those that are decomposed with another ozone molecule according to the equation.

and those that communicate their energy to foreign molecules. These cause the reaction to be checked. But energy cannot thus be conferred in the same

¹ Trans. Faraday Soc., 20, 530 (1925).

³ Bonhoeffer: Z. Physik, 13, 94 (1923).

⁴ Regener: Ann. Physik, (4) 20, 1033 (1906); v. Bahr: 33, 598 (1910); Weigert: Z. physik. Chem., 80, 78 (1912); Warburg: Ber. preuss. Akad. Wiss., 1913, 644; Griffith, Shutt, McWillie: J. Chem. Soc., 119, 1948 (1921); 123, 2752, 2767 (1923).

manner on all foreign molecules. The collisions possess the highest degree of elasticity in the case of helium and argon, a smaller degree in nitrogen, and the least in oxygen. Thus the kinetics of the photochemical decomposition of ozone bears a strong resemblance to the fluorescence of iodine and mercury vapour. The individual gases appear in a similar order in the case of the extinction of the fluorescence as when they receive energy from stimulated ozone molecules."

Allmand¹ has developed a chain mechanism for this case which pleases him very much. "One of the most remarkable facts in connection with certain photosensitised reactions in which a halogen is the absorbing component is the way in which the rate of reaction is independent of the concentration of the decomposing or reacting constituent. As examples may be mentioned the oxidation of CCl_3Br in CCl_4 solution by oxygen when sensitised by dissolved bromine,² and the photodecomposition of ozone in presence of bromine.³ The best-known case is the corresponding ozone-chlorine decomposition,⁴ which will be briefly considered in this paper. Here the reaction, in respect of ozone, is of zero⁵ order, and remains so until decomposition is complete within the limits of accuracy of measurement. So far as the writer is aware, there is no known case in which a non-absorbing component enters into a photochemical reaction with order other than between the limits 0-1, tending of course towards zero at high concentrations. But the example now under discussion seems rather too pronounced to be regarded simply as an extreme case of a general rule—one would certainly expect, judging from other instances, some indication in the experimental curve towards the end of the reaction of a change in order from zero to unity."

"The mechanism of ozone decomposition, under the conditions postulated, will be as follows:—(1) formation of activated Cl_2 molecules (Cl_2^*) by light absorption; (2) collision between Cl_2^* and O_3 molecules resulting in deozoneisation and energy degradation; (3) collision between Cl_2^* and O_2 molecules, resulting in the formation of activated O_2 molecules (O_2^*); (4) collision between O_2^* and O_3 molecules, resulting in deozoneisation and energy degradation. Other processes which will certainly occur are:—(5) spontaneous degradation of quantised energy held by Cl_2^* molecules, and (6) spontaneous degradation of quantised energy held by O_2^* molecules. Collisions between (7) O_2^* and O_2 molecules and between (8) Cl_2^* and Cl_2 molecules will be assumed to have as result, if any, simply the transfer of the quantised energy from one molecule to another of like kind,⁶ and hence not to change the composition of the system. Finally, as when a Cl_2^* molecule activates an O_2 molecule by collision, it is likely that the whole quantum is not transferred as such to the O_2 molecule, but rather that a portion of it is lost as low-grade radiation (*i.e.*, the

⁵ Not of first order, as stated by Norrish and Rideal.

⁶ Franck: Z. Physik, 9, 259 (1922).

quantum associated with an O_2 molecule is smaller than that associated with a Cl_2 molecule), it seems reasonable to assume that (9) a collision between an O_2 and a Cl_2 molecule will not result in Cl_2 formation."

"The mechanism here suggested appears to have two advantages over those proposed by Bonhoeffer¹ and by Weigert.² Firstly, it takes into account the deoxygenation of O_3 molecules by the O_2 molecules, which the work of Norrish and Rideal has shown to be, in all probability, formed under the conditions of the experiment; and secondly, it accounts for the course of the experimental curve, which other explanations fail to do. The assumptions involved in processes (7), (8) and (9), appear reasonable enough, whilst Bonhoeffer himself was forced (unwillingly) to conclude that the life of a Cl_2 molecule must be unusually long. Weigert's mechanism of "isochromatic fluorescence"³ enables him, of course, to avoid this conclusion."

There seems to be no question but that chlorine acts catalytically, in the sense that there is no permanent change in the chlorine during the reaction. Instead of starting from the Einstein hypothesis and inventing ingenious chain mechanisms which seem not to be susceptible of proof in the present state of our knowledge, one wonders whether it might not be wiser to start from the fact of a zero-order reaction and later to work out the quantum relations.

In order to have a zero-order reaction, the concentration of everything that counts must remain constant during the reaction. We get this, for instance, when hydrogen and chlorine react at constant pressure in presence of liquid water, because the hydrochloric acid is taken up by the water and consequently the concentration of the hydrogen and chlorine do not change. In the sensitization of the ozone decomposition by chlorine, the ozone concentration does change and therefore what we are measuring is not the rate of decomposition of ozone. The combined rates of activation and de-activation of chlorine must be slow relatively to the rate of decomposition of ozone by activated chlorine. This may prove to be an untenable hypothesis; but it should be considered.

It is clear that we have two classes of optical sensitizers, one which is merely a disguised chemical sensitizer and one, like the chlorine and ozone, where there is a transfer of energy in some way without any permanent

¹ Z. Physik, 13, 94 (1923).

² Z. physik. Chem., 106, 407 (1923).

³ The fact referred to early in this paper that the order according to which a non-absorbing component enters into a photochemical reaction always lies between 0-1, is of interest in connection with this conception of Weigert's. For, to take the case when all the incident light is absorbed, a photochemical reaction rate will then be represented by an equation of the type—

$$\text{Rate} = K(1 - e^{-kc}),$$

where c is the concentration of the non-absorbing component in question, and k a reaction velocity constant similar to k_1, k_2, k_3 above. k thus has, in any case, a formal resemblance to an ordinary radiation extinction coefficient, and of course must actually be such a magnitude if the Weigert conception holds. Whether an O_3 molecule is deoxygenized by collision with a "free" quantum or with one associated with a molecule such as Cl_2 or O_2 naturally makes no difference to the type of equation which expresses the results.

change taking place in the sensitizer. We do not know how the transfer of energy takes place and we have no theory as yet as to what kind of substance will transfer energy in this or any similar way. A copper sulphate solution for instance absorbs certain wave-lengths very strongly. Will it act as an optical sensitizer for any reactions and, if so, for what reactions?

It is worth noting, however, that in all cases, no matter how involved, the law of Grotthuss holds that only the light which is absorbed is effective. A very interesting case of this is to be found with chlorophyll which shows a strong absorption band in the red, divided into two in the case of chlorophyll-*b*.¹ "The chief absorption is in the longer wave-lengths and is practically in the position of the maximum energy of the solar spectrum, during the greater part of the day. S. P. Langley's measurements of the position of maximum energy gave 650-666 $\mu\mu$ for high sun. The latter number is easy to remember, as Timiriazeff points out, being the 'number of the beast.' The middle of the chief band of chlorophyll-*a* is, in solution in ether, at 662 $\mu\mu$. In colloidal solution in one percent acetone, the band is shifted toward the red, so that its maximum is at 678 $\mu\mu$. This is the same as that of its natural state in the leaf. [According to Willstätter, chlorophyll probably exists in the leaf as an adsorption compound with a colloid, but not combined with a lipoid, as some have stated.] The maximum energy of solar radiation, also, would be for the greater part of the day nearer the red than the figure of Langley. Chlorophyll has a considerable absorption in the blue also, but practically none in the infra-red, nor in the yellow-green, and not much in the ultra-violet.

"It is remarkable that some of the earlier observers believed that the maximum photochemical change occurred in the yellow-green region, in which the absorption of light energy is minimal. This would be a difficulty in view of Grotthuss' law, and later observations, especially by Engelmann, showed it to be due to the incorrect estimation of the absorption of the screens used.

"A striking demonstration of the fact that the maximum evolution of oxygen is at the place of the greatest absorption of light was given by Engelmann.² This was done by the use of a bacterium, which was very sensitive to oxygen. Water containing these organisms was placed, along with a thread of a green alga, on the stage of a microscope. In the same plane, and along the thread of alga, a minute spectrum was projected by means of a spectroscopic arrangement beneath the stage. It was seen that the bacteria accumulated precisely at the places where the absorption bands of chlorophyll were situated.

"Another experiment showing the same fact, is due to Timiriazeff.³ A leaf on a plant is deprived of its stored starch by being kept in the dark. A small spectrum is projected on to its surface and, after some time, the leaf is decolorised by alcohol and treated with iodine. The absorption bands of chlorophyll are then found to be mapped out by the action of the iodine on

¹ Bayliss: "Principles of General Physiology," 562 (1915).

² Onderzoek. Physiol. Lab. Utrecht, 7, 191 (1882).

³ Proc. Roy. Soc., 72, 424 (1903).

the starch, which has only been formed in these places. Measurements have also been made, spectrophotometrically, of the absorption of light in different regions of the spectrum and compared with the photochemical effect. There are two maxima shown; but, when the curve is corrected for the normal spectrum, in which equal abscissas correspond to equal differences of wave-length, the second maximum in the blue end is found to be comparatively unimportant. . . . We may take it, then, that the maximal effect of the chlorophyll system is in relation to that part of the spectrum which is absorbed most."

Bayliss¹ calls attention to the fact that "the absorption of light by chlorophyll is such as to make the best use of the light available. But a green pigment is, of course, transparent to the green rays, which preponderate under water, so that it would be inefficient in that situation. Accordingly, as Engelmann² has pointed out, we find, in the seaweeds, red and brown pigments corresponding to chlorophyll and having the same function, but able to absorb effectively the green light available. For example, the red seaweeds show a maximum of carbon assimilation in the green and, spectrophotometrically measured, they show the greatest absorption in the same region, although there is also considerable absorption between the lines B and C, where the chief band of chlorophyll lies. The minimum of absorption is in the orange between C and D. This fact serves to illustrate the function of chlorophyll as an optical sensitizer; the same effect is produced by light of various wave-lengths, provided it is absorbed."

Eosin may change the wave-length of light necessary to kill bacteria.³ "Although ultra-violet light has so much more action on protoplasm than visible light has, it has been found by several observers that light which has no action by itself on infusoria, bacteria, or blood produces the effect of ultra-violet light when certain dyestuffs are present. Although the dyes used were, for the most part, fluorescent, this does not seem to be an essential factor. For a complete account of the work, the reader is referred to the monograph by Tappeiner and Iodlbauer.⁴ The general nature of the phenomenon will be clear from the few remarks following. Hertel⁵ exposed certain bacteria to light of 448 $\mu\mu$. This had no effect on them, either with or without the presence of eosin, 1 : 1200. Eosin has no absorption band in this position. Ultra-violet light of 280 $\mu\mu$ killed them in sixty seconds, without eosin. A third experiment consisted in taking light of 518 $\mu\mu$, that is, in the position of the absorption band of eosin, and making it of about the same energy as the ultra-violet light previously used. Alone, this light had no effect, as would be expected, since it has a longer wave-length than that found ineffective in the first experiment. On the other hand, in the presence of eosin, which has no action in itself, as the first experiment showed, the bacteria were

¹ "Principles of General Physiology," 567 (1915).

⁴ "Die sensibilisierende Wirkung fluoreszierender Substanzen," (1907).

⁵ Z. allgem. Physiol., 5, 95 (1905).

killed in seventy to ninety seconds. It appears that the action of the eosin is to be compared to that of an optical sensitizer."

Where it is possible for a substance to change color, the effect of colored light should be to change the substance to the same color as the light, provided there is no disturbing factor. This case has been realized by Wiener¹ with photochlorides. With the fulgides Stobbe² found³ that "orange light produces an orange dye and blue light a blue one. Thus, a substance is formed which does not absorb the light acting, so that no further change takes place; although if the product is exposed to light of a different wave-length from that under which it was produced, further change is effected since the light is absorbed." Bayliss has gone a bit beyond his facts. Blue light may have produced a blue dye; but the visible color was brown.

If we are dealing with a living organism, the reaction may be, and sometimes is, to produce a pigment, or more of a pigment, which will be complementary to the impinging light and which will keep the light from penetrating into the tissue. Light, which is absorbed by chlorophyll, tends to bleach the pigment but it also stimulates the formation of it.⁴ "There is evidence to show that, under the influence of light, the chlorophyll in a living cell is constantly being destroyed, but that under normal conditions the leaves remain green, the chlorophyll being reconstructed as fast as it is destroyed. Thus when leaves are exposed to a stronger light than usual, they become paler in colour, probably owing to the fact that under these conditions the chlorophyll is destroyed at a more rapid rate than it is reconstructed. This is frequently observed in the leaves of shade plants when exposed to bright sunlight, and is also observed in Algae such as *Spirogyra* which accumulate near the surface of water in the intense light of the sun during the summer months."

A more striking case is cited by Bayliss⁵ who seems to be a little puzzled by the formation of the complementary color, apparently not distinguishing between adaptation by a living organism and the normal elimination which we get with chemical compounds. "In certain cases, to which Engelmann⁶ has given the name of 'complementary chromatic adaptation,' we find that a pigment is actually formed under the action of coloured light and that the pigment has a colour which is complementary to that of the light to which the organism is exposed, so that this light is then absorbed. The alga, *Oscillaria sancta*, as shown by the work of Gaidukov,⁷ occurs in several colours between reddish purple and blue-green. If cultures are made, say, of the reddish-purple variety, we find that under red light a green pigment is produced. If we take the green variety; it becomes reddish under green light, brownish-

⁷ "Ueber den Einfluss farbigen Lichts auf die Färbung lebenden Oscillarien" (1902).

yellow under blue light, and so on. The work was done with great care and spectro-photometer curves of the various pigments were compared with those of the light under which they made their appearance."

These illustrations should be sufficient to prove the accuracy of the original postulates that only that light which is absorbed can be effective, and that all absorbed light tends to eliminate the substance absorbing it. It is entirely a question of chemistry whether any reaction takes place or what the reaction products are. I find that the silver salts bother some people unnecessarily, because the silver salts are moderately transparent while metallic silver is quite opaque. They overlook the fact that light is fairly efficient with silver salts in presence of a depolarizer, whereas it would be difficult to specify what reaction could take place between silver and gelatine.

We see that absorbed light may do one or more of three things. Under favorable conditions it may cause visible chemical change; under unfavorable conditions the absorbed energy may be converted completely into heat; under conditions which we cannot specify accurately at present a portion of the absorbed energy may appear as luminescence, either as fluorescence or as phosphorescence.

This last paragraph can be, and has been, said at much greater length if one speaks in terms of quanta. We will begin with a quotation from Bodenstein.¹ "To develop the kinetics of photochemical reactions let us analyse the process of light-absorption and its resulting effects. Nowadays we know that the absorption takes place in quanta; one molecule absorbs one quantum of energy. If the rays absorbed are visible or even ultra-violet, the energy thus conferred on the molecule is very considerable. It is of the order of the average energy of molecules at a temperature of some thousand degrees. Nevertheless in most cases the only result is the transformation of the energy into increased thermal motion. It is not sufficient to stimulate a chemical reaction.

"Yet, even if this is the case, every act of absorption need by no means be followed by a chemical reaction. Even then the molecule can communicate its increased energy to others in the shape of thermal motion, or again it can lose it by fluorescent radiation, or it can indeed employ the energy to effect a chemical reaction.

"As to the manner in which this occurs, the most obvious conception is that the energy is employed directly to sever an atom from the molecule; and this view has indeed often been taken.² But there are grave reasons against the conception. First, the energy that can be conferred on the molecule without effecting a severance is considerably greater than the work of dissociation.³ Secondly, radiation of energy as fluorescent light is possible, when the absorbing substance is a very dilute gas. This fact forces us to conclude that the molecule tends to radiate its surplus energy, in as far as it has no opportunity of communicating it as "flight"—energy to other molecules by collision

¹ Trans. Faraday Soc., 20, 526 (1925).

² Warburg: Sitzungsber. Akad. Wiss. Berlin, 1916, 324; 1918, 300.

³ Stern and Volmer: Z. wiss. Phot., 19, 275 (1920).

shortly after the act of absorption has taken place, or of accommodating itself to its increased energy during the collision by dissociation or some similar chemical reaction.

"This "competition" between fluorescence and communication of energy to other molecules has been observed in the vapours of iodine¹ and of mercury.² If the period between two collisions goes below the order of 10^{-8} sec., the fluorescence is extinguished more and more. Other observations have also given 10^{-8} secs. as the approximate term of life in the stimulated state.

"A similar competition between fluorescence and photochemical reaction has, so far as I know, not yet been observed. Photochemical processes have not yet been investigated at sufficiently low pressures. However, these investigations are soon to be expected, for they have been rendered urgent by the development of "dark reaction" kinetics.

"Up till now only such investigations have been made as could be carried out with high concentrations, *i.e.* short periods between two collisions. So here there can only be a question of competition between chemical reaction and communication of energy to other molecules. And here it has been found that in most cases the latter is quite inconsiderable."

It does not seem to me that Franck³ is much more helpful. "The researches of E. Warburg⁴ together with a great number of experiments of other workers carried out in recent years, have shown that the Einstein law of equivalence holds for primary photochemical reactions. By primary reaction is understood the first stage of a chemical reaction, for example the breaking down of a diatomic molecule into its component atoms. This occurs if the molecule has absorbed an amount $h\nu > D$, where D is the work of dissociation.

"Stern and Volmer⁵ were the first to show that from the physical standpoint the primary reaction is not the first elementary process, which consists rather in the excitation of a molecule, *e.g.*,

The conversion of excitation into chemical energy occurs only by collisions of the excited molecule with any other atom or molecule, provided that the collision takes place during the period of excitation. We have here a special case of a collision of the second kind. Otherwise the energy will be partly or wholly re-emitted by radiation in accordance with the Bohr frequency conditions, when we have the case of fluorescence instead of photochemical action.

"Indeed the experiments on gas fluorescence⁶ and on the excitation of molecular spectra by impacts of electrons,⁷ which are in many respects very

similar, show that at low pressure a molecule may take up many times its dissociation energy without dissociating. For example iodine can absorb and re-emit as a resonance spectrum an amount of energy five times the work of dissociation, when illuminated by the line λ_{1849} .¹ From the position of the longest wave-length member of the resonance series we can deduce that here at the maximum half the energy of dissociation can remain in the form of nuclear oscillations. A further example is to be found in the hydrogen molecule which, on excitation by electron collision, can emit as molecular spectrum four to five times the amount of the dissociation energy. If we consider also the experiments on the excitation of X-rays spectra which, due to secondary effects such as expulsion of electrons, are not so easy to interpret, we may arrive at values of the excitation energy which may exceed the work of dissociation a thousand times without leading to dissociation by a primary process."

"The well-known explanation of this effect is that the excitation energy is primarily employed in raising the electron to a higher quantum state, while the oscillation and rotation energies are only altered by the coupling of their periods with those of the electron system. It is, indeed, possible in heteropolar molecules for the oscillation and rotation energies to change by light absorption without simultaneous changes of quantum number of the electron system, but the energy of such changes is so small compared with that of dissociation that it may be neglected.

"Consequently the question whether a photochemical dissociation is possible in one elementary act, that is without collision with molecules which chemically take no part in the reaction, is reduced to a consideration of the magnitude of the oscillation and rotation energy changes, which are coupled with the changes which the electron system undergoes on absorption of light. Only when this amount equals or exceeds D for the state considered can dissociation take place. We will deal later with the question of into what parts the molecule can dissociate. We must first consider whether and under what conditions we can give large quantities of rotation and oscillation energy to the molecule.

"Lenz has developed a theory which is concerned with the coupling of the electron with the molecular frequencies, and concludes that the rotation quantum number can only change by ± 1 , on the occasion of an electron jump.² We may therefore neglect the influence of rotation. He has also shown how the alteration in oscillation quantum number may be understood by reference to the correspondence principle.³

"We can consider this question more qualitatively but more generally. We may assume that, when light is absorbed, the nuclei can only alter their potential energy, as the raising of the electron system to another quantum state alters the strength of the chemical binding of the molecule. This change

¹ O. Oldenberg: *Z. Physik*, **18**, 1 (1923).

² Lenz: *Physik. Z.*, **21**, 691 (1920).

³ Lenz: *Z. Physik*, **25**, 299 (1924).

may be large or small, positive or negative. A schematic diagram of the potential energy of the nuclei, u , as a function of their distance apart, r , allows us to review the possible cases more easily."

"Before we proceed to show that the observations agree with our expectations, we must discuss into what parts the molecule can break down on absorption of light, which is the same question as what parts of the molecule are oscillating relative to one another in the relevant excited state.

"In heteropolar molecules we know that in the normal state of the electron system, positive and negative ions are oscillating, and if we consider such a molecule to be disrupted by an adiabatic process, we shall have a dissociation into a positive and a negative ion. In a higher quantum state, where an electron of the positive ion is raised to a higher quantum orbit, the binding will be stronger, and we can expect no dissociation by absorption of light. Whether we can remove an electron by radiation from the anion will remain uncertain so long as an electron affinity spectrum is unknown. In any case it is a matter not of excitation, but of the complete removal of an electron, and as the binding will of course be very weak we shall have a dissociation into a positive ion, an electron and a neutral atom. The result is sufficient for us that an adiabatic separation of the molecule on excitation into its component atoms is not possible. A fuller discussion of the excitation of the band spectra of heteropolar molecules will be found in a recent paper by Mulliken.¹

"We know at present very little also about the binding of homopolar molecules. We have two possibilities to discuss.

"The first and simpler of the two is that in which the atoms of the molecule are bound together by the van der Waals forces. As Debye² has shown, free atoms in the act of collision may polarise each other, or so arrange their existing moments, that an attraction ensues. If the same process takes place in these molecules the orbits will be disturbed; but the quantum numbers of the electron system will be preserved in the molecule. Such molecules can be adiabatically disrupted into normal atoms, and in the case where the atoms are of the same kind, the work of dissociation will be of the order of magnitude of the atomic heat of vaporisation.

"When such a molecule is excited by light, the electron of one of the atoms will be raised to a higher quantum orbit, and with weak bindings the wavelengths associated with such transitions will be almost identical with those emitted by the free atoms. In fact, all very loosely bound compounds like Na_2 and Hg_2 show such a relation, and the bands attach themselves closely to the atom lines.

"In the mercury molecule not only the lines due to the transitions $1.5\text{ S} - 2\text{p}_2$ and $1.5\text{ S} - 2\text{P}$ exist (as can be seen from the fact that the bands attach themselves to these absorption lines) together with further atom lines which are found accompanied in emission by bands, but also the metastable states

¹ Mulliken: *Phys. Rev.*, **26**, 1 (1925).

² Debye: *Physik. Z.*, **21**, 178 (1920).

of the atom are metastable in the molecule.¹ Plainly these facts are related with the smallness of the work of dissociation, which is of the order of 1 kilocalorie. In absorption these bands are found on the long wave-length side of the absorption lines, which shows, as mentioned above, that the binding is stronger in the excited state. Attached to these unresolvable bands are continuous spectra stretching in the long wave-length direction over a wide region. From this we may conclude that not only the oscillation energy existing in the initial state can be used to raise the electron system to a higher quantum state, but that also the kinetic energy of two impacting free atoms can be called into service.² Expressing this in the form of an equation we obtain:—

$$\begin{aligned} &\text{Kin. relative energy of atoms} + (\text{heat of dissociation})\text{Hg}_2 \\ &+ h\nu = (\text{Energy of excitation})\text{Hg}_2. \end{aligned}$$

“Here we may have then a photochemical elementary act in which two colliding atoms, by the influence of light absorption, unite in an excited molecule, in the manner to be expected from Diagram III.³

“Conversely, we should have in molecules in which the potential energy of the nuclei follows the relations shown in Diagram I³, the possibility that the molecule may take up so much oscillation energy through absorption that it parts into a normal and an excited atom.

“Of course such a process is only possible in a molecule which is capable of separating adiabatically into these components, and it appears that the halogen molecules belong to this class. Accordingly they should belong, certainly in the excited and probably also in the normal state, to the type of molecule bound together by van der Waals forces, and indeed their relatively small work of dissociation is in complete agreement with this view.”

“If our assumptions are correct, an accurate analysis of the terms of the halogen spectra would naturally lead to very accurate values of the work of dissociation of the halogen molecules, from purely spectroscopic data.

“Dymond, working in my Institute, has, in a paper shortly to be published, given further reasons why light of a wave-length covered by the continuous absorption spectrum can bring about dissociation of iodine. The principal argument is that we are forced to conclude that the emission of series of resonance lines on illumination with a series of wave-lengths, from long waves to the neighbourhood of $\lambda 5000$, consists of molecular fluorescence

“Wave-lengths shorter than $\lambda 5000$ give no trace of fluorescence, although they are more strongly absorbed than in the region of band absorption. He also describes a luminescence due to recombination of normal atoms with those in the metastable state. That the transition $2p_2 - 2p_1$, may take place

¹ From this we can explain the long afterglow of the molecular fluorescence of mercury, first noticed by Philips (Proc. Roy. Soc., **89A**, 39 (1924)) and also the fact that the luminescence is only emitted by the influence of collisions. See Franck and Grotrian: *Z. Physik*, **4**, 89 (1921).

² Born and Franck (*Z. Physik*, **31**, 411 (1925)) maintain that in this case only unstable quasi-molecules can be formed. This limitation is not necessary for molecules which are built up by normal atoms bound together by the van der Waals forces.

³[Not given in this report.]

spontaneously in the molecule although forbidden in the atom is to be explained from the strong electrical disturbances of the atoms of the molecule on each other. The work of dissociation, and therefore the electrical disturbances, are here much greater than in the mercury molecule.

"In conclusion we must mention the second possible type of homopolar molecule and a few arguments for its existence.

"In this class the electron system of the atom is not only disturbed but quite new orbits of the electrons appear which belong to totally different types of motion from those of the free atoms. As an example, let us take the assumption frequently made that two or more electrons are common to both atoms of a diatomic molecule; the orbits cross in some way and encircle both nuclei. Such molecules can certainly not separate from the normal state adiabatically into two atoms, and the electron jumps associated with the formation and dissociation of these molecules cannot be produced by radiation processes but only through the energy of collisions. Here we should expect a considerably greater value for the dissociation energy, as indeed is the case in nitrogen and oxygen.

"Recently Blackett and the author, in a paper shortly to be published, have more closely examined the hydrogen molecule. No point of convergence of bands has been observed in the molecular spectrum of hydrogen. Together with other reasons we can take this as indicating the impossibility of adiabatic separation of the atoms.

"Through the influence of collisions, which as is known can cause transitions of the electron orbits between different classes of mechanical orbits, it has been shown in the paper mentioned that the hydrogen molecule can dissociate into a normal and an excited atom. An adiabatic separation is possible as soon as a transition of the electron system into that of the atom has occurred through the collision process."

Ornstein¹ says that "in the photochemical process excited molecules are formed by light, collisions transform the energy absorbed by the quantum absorption into chemical energy; in the second stage newly formed molecules lose their energy by way of emission."

Roy² states that "molecular collisions have no place in unimolecular reactions. 'Activation' is a preliminary process of 'loosening of the chemical bonds' between the two components of a molecule and may result from absorption of radiation (endothermic reaction) or emission of radiation (exothermic reaction) according to whether it is necessary for the binding electrons to move to higher or lower quantum states to render the molecules reactive. A molecule, presumably, passes through a series of quantised states by absorption or emission of some definite frequencies before coming to a final 'reactive' state. A 'reactive' molecule subsequently undergoes decomposition by absorption of radiation of all frequencies greater than a certain limiting value. For the steady continuance of the reaction it is necessary that the

¹ Trans. Faraday Soc., 20, 505 (1925).

² Trans. Faraday Soc., 20, 523 (1925).

process of 'activation' must run at a rate sufficient to furnish the number of 'reactive' molecules necessary for the reaction. A satisfactory law of uni-molecular reactions can easily be worked out¹ on the basis of these ideas."

Kautsky² has discussed chemiluminescence. "Haber and Zisch³ have investigated the luminescence caused by the combination of sodium vapour with chlorine and have explained it theoretically. My colleague Dr. Zocher and I⁴ gave independently a similar explanation for the extraordinary bright chemiluminescence which is caused by the oxidation of silikone at room temperature. (Silikone is a yellow solid substance, a mixture of siloxen ($\text{Si}_2\text{O}_3\text{H}_6$) and several coloured reaction products of siloxen.) This explanation may be expressed briefly in the following way. The energy which is set free in any chemical reaction remains first associated with the reaction products. In the simplest case of chemiluminescence the reaction product itself may give off its energy, or at least a part of it, in the form of radiation. In other cases we may first have a transfer of energy without radiation from the reaction products on neighbouring molecules. These molecules may be molecules which take part in the reaction or molecules of another kind. By this transfer of energy, they are transformed into an unstable active modification, richer in energy, and light is emitted when they return to their normal states.

"Chemiluminescence is therefore the reversal of a photochemical or a sensitised photochemical reaction. Here the absorption of light causes directly a chemical reaction or, in the case of sensitisation, it causes a chemical reaction in consequence of a transfer of energy on neighbouring molecules⁵. Chemiluminescence only differs from fluorescence in so far as the activation is of a different kind. In the case of chemiluminescence it is the energy of a chemical reaction which causes the radiation, in the case of fluorescence it is the absorbed light which has the same effect.

"It therefore ought to be possible to force a substance which shows fluorescence to give chemiluminescence by using suitable reactions for activating its molecules. We might expect then that the spectrum of chemiluminescence would be identical with the spectrum of fluorescence. Experiments were therefore made to force fluorescent dyestuffs like rhodamine and rhodamine sulphonate to give chemiluminescence. In order to attach this end the following conditions have to be fulfilled. We need a reaction which gives the energy necessary to activate the dyestuffs and which does not change their emission of light. We further need conditions in order that the transfer of energy from the place of reaction to the molecules of the dyestuffs is thorough and effective. These conditions are fulfilled by some solid colourless derivatives of silicon, for instance silico-oxalic acid siloxen and some colourless oxidation

⁵ The correlation between chemiluminescence, sensitisation and photochemical reactions has been investigated by Kautsky and Thiele: Z. anorg. Chem., 144, 197 (1925).

products of siloxen.¹ These latter derivatives of silicon have a strange morphological structure.² They are built up of lamellae consisting of layers of molecules only one or two molecules thick. These layers lie over one another like the leaves of a book. They adsorb basic dyestuffs in water solution. The adsorption compounds are strongly coloured and show fluorescence. The lamellae themselves may be oxidized by adding small amounts of potassium permanganate in acid solution without showing luminescence and without change in their morphological structure. The energy of this oxidation is easily transferred to the dyestuff molecules since they are adsorbed on the lamellae. They are, therefore, in the direct neighbourhood of the places of reaction.

"The chemiluminescence which is caused by adding a solution of permanganate to these adsorption compounds is suprisingly bright. The same chemiluminescence is found if these adsorption compounds, in a dry state, are oxidised with ozone. This shows that it is the adsorbed dyestuff which causes the chemiluminescence. The dyestuffs were made to fluoresce by illuminating them with ultra-violet light. There was no difference between the fluorescent spectra of the adsorption compounds and of the dyestuffs in solution.

"The above-mentioned theory was verified quantitatively in so far as the chemiluminescent spectra of rhodamine and rhodamine sulphonate were found to be identical with their fluorescent spectra."

Lindemann³ considers that there were two totally different problems in the discussion before the Faraday Society. "The one set of problems is connected with the secondary effects following upon photochemical activation. Here we have a long, often complicated, chain of reactions, whose investigation is more a matter for the chemist than the physicist at the present stage.

"By contrast the primary reaction seems to me to be comparatively simple and in good accord with Einstein's law, the so-called deviations being due to a misapprehension of what is claimed. When one quantum of light is absorbed by an atom it moves the electron from one stationary orbit to another stationary orbit, or ionises it completely, as in the photo-electric effect. The excited atom can give up its store of energy in various ways, either by the return of the electron to the primary orbit with emission of radiation, as occurs in the phenomena of fluorescence or phosphorescence, or by the transfer of the energy to kinetic energy of some atom with which it collides (*Stoss zweiter Art*), or by taking part in some chemical process. Einstein claimed that every atom must be photochemically affected. His law merely gives the maximum number which can take part in the primary reaction. The chance of a photochemical reaction taking place depends upon the excess of the energy of the quantum over the energy of activation. Thus the efficiency of the light will in general increase as the frequency is increased,

³ *Trans. Faraday Soc.*, **20**, 607 (1925).

and may have any value between 100 percent and 0 percent as the long wave limit is approached."

I do not myself believe that it is possible, as Lindemann and others assume, to keep an electron long enough in an outer orbit to give rise to chemiluminescence. If this cannot be done, we must recognize that there are two types of fluorescence, as indeed there are. The cathode ray fluorescence of mercuric bromide, cadmium sulphate, and lead sulphate involves the actual decomposition of these salts into mercury and bromide, cadmium oxide and sulphur trioxide, and lead and sulphate radical respectively; but nobody would guess it from the discussion, and consequently I, for one, do not feel inclined to accept at their face value the views which I have just quoted at some length. I should like to see a little more definite knowledge.

Having acquired a fairly definite idea of the general principles governing photochemical change, we can finish up the nominal subject of this report in short order, because the theory of the displacement of equilibrium by light is quite simple.¹ If we expose a system to a given light of given intensity, the light which is absorbed will tend to eliminate the substance absorbing it and will do so if the conditions are favorable. We will suppose that x grams of the absorbing substance would be changed in the first second if there were no disturbing factors. The two disturbing factors are the reverse reaction in the dark and the reverse reaction due to the absorption of light by the photochemical conversion products. If we postulate that these two reverse reactions produce y and z grams respectively of the original substance in the first second, the total conversion in the first second will be $x - y - z$ grams. Theoretically, we can eliminate the reverse photochemical change by using only the wave-lengths which decompose the original substance. In this case the amount of conversion in the first second will be $x - y$ grams and will be zero when $x = y$. In other words, the favorable condition for getting a marked displacement of equilibrium is that the reverse reaction shall be very slow. The monomeric form of nitrogen peroxide has a very strong band in the more refrangible end of the spectrum; but it would probably be impossible to produce a perceptible bleaching by the blue light because the reverse reaction is too rapid. Ozone is formed photochemically from oxygen by some of the wave-lengths less than $200\mu\mu$ and is decomposed photochemically by some of the wave-lengths² longer than $200\mu\mu$. Since we have no ray filter which will let through the wave-lengths shorter than $300\mu\mu$ while cutting off those longer than $300\mu\mu$, the amount of ozone formed in the first second by any given light is $x - y - z$ grams. Since the temperature coefficient of the reaction in the dark is usually much greater than the temperature coefficients of the photochemical reactions, we can usually decrease y relatively to $x - y$ or to x by lowering the temperature. This is actually the case with ozone. At low temperatures we can get a fairly good yield of ozone, while there is practically no ozone formed at 200° because the decomposition is so rapid.

¹ Cf. Sheppard: *Chem. Rev.*, 4, 319 (1927).

² For decomposition of ozone by red light, see Kistiakowsky: *Z. physik. Chem.*, 117, 337 (1925).

Violet light converts the ordinary dissolved sulphur¹, S_{λ} , into the insoluble sulphur, S_{μ} . The amount of conversion decreases with rising temperature because the speed of the reverse reaction in the dark increases. Wigand was only able to get a lowering of the freezing-point of sulphur of a few tenths of a degree by exposure to light; but it is possible that one could do better than this because Wigand did not use the most favorable wave-lengths.

Water is a mixture of compounds having the general formula $(H_2O)_n$. Some of them must absorb some rays in the ultra-violet more strongly than the other modifications do, in which case it should be possible, theoretically, to displace the freezing-point of water. Whether one can get a measurable displacement depends on the rate of the reverse reaction. One could undoubtedly get results with some of the aldoximes.

Similarly it is possible, theoretically, to displace the inversion temperature for the red and yellow mercuric iodides; but there are no data to show whether the displacement would be measured in degrees or in thousandths of a degree. Dey² finds that the orange-yellow $(HgS)_2.HgI_2$ turns black on exposure to sunlight and reverts in the dark. One factor in making possible the decomposition of mercurous chloride into mercury and mercuric chloride is that the reverse reaction takes place slowly in the dark. Sazaki³ reports that light displaces the equilibrium between ferrous salt and iodine towards the iodide side.

Coehn and Becker⁴ have studied the effect of light on mixtures of sulphur dioxide and oxygen. The effective light does not exceed $265\mu\mu$ in wave-length, which makes it practically impossible to use uviol glass and actually there is almost no effect in uviol glass. Equilibrium was reached from both sides in presence of ultra-violet. With a quartz mercury lamp as source of light the photochemical equilibrium is at about 65% conversion at 160° , as against 100% conversion for thermal equilibrium in presence of a catalyst. Coehn and Becker say that the photochemical equilibrium is practically independent of the temperature up to 800° , where the thermal conversion in presence of a catalyst is only about 30%. With a ratio of $SO_2 : O_2 = 1 : 13$ they obtained a conversion of 80% at 800° as against a catalytic one of 44%.

Over this whole range of temperature the rate of conversion or decomposition is practically zero in the dark in absence of a catalyst. The reverse reaction, y , in the dark therefore drops out practically completely in these experiments, as Coehn and Becker themselves state. Since the rate at which equilibrium is reached in the light increases enormously between 160° and 800° with a temperature coefficient of 1.2, the only way in which a displacement of equilibrium can be avoided is by postulating that one is measuring the antagonistic action of two groups of wave-lengths, just as we know we do in the ozone formation. The effects of both sets of wave-lengths must increase proportionally with the temperature.

¹ Rankin: *J. Phys. Chem.*, 11, 1 (1907); Wigand: *Z. physik. Chem.*, 65, 442 (1909); 77, 423 (1911).

² *Nature*, 112, 240 (1923).

³ *Z. anorg. Chem.*, 122, 61 (1922).

⁴ *Z. physik. Chem.*, 70, 88 (1910).

Instead of adopting this obvious explanation, Coehn and Becker assume that there cannot be antagonistic groups of wave-lengths in this case, that probably there are not in any case, and that, consequently, the ozone work is wrong. They ignore the fact that their position is unsound theoretically and that it does not account for their own experimental observation that the photochemical equilibrium is not displaced appreciably by change of temperature although the rate of reaction is.

In the Cornell laboratory we have obtained a conversion of only about 25% at a little under 200°, passing a Tesla oscillatory discharge through the gas, which probably gives us a different group of wave-lengths in the ultra-violet. This is not inconsistent with Coehn and Becker's experiments; but is quite inconsistent with their assumptions.

Chapman, Chadwick and Ramsbottom¹ have shown that dry carbon dioxide at atmospheric pressure is decomposed 2.5-3.0 percent by ultraviolet light, while at 36 mm pressure 46 percent of the carbon dioxide is decomposed. The main reaction is, of course, $2\text{CO}_2 \rightleftharpoons 2\text{CO} + \text{O}_2$; but some of the oxygen is converted into ozone. When moist carbon dioxide is used, there is practically no decomposition at all. Ellis and Wells consider that under these conditions "the catalyst (moisture) exerts a marked influence in determining the mode of distribution of energy among the molecules of the reacting substances (the two oxides of carbon and oxygen)." This sounds well, but do we know that water vapor does act as a catalyst at these temperatures? It is quite as possible that the water vapor acts as a screen. The experiment should be repeated with concentric tubes and the water vapor in the outer one. Then we should have something definite to go on.

Coehn and Sieper² have also studied the action of ultra-violet light on carbon dioxide. The wave-length of the active rays lies below 254μ . When the pressure is such that the dry gas is decomposed to the extent of 18 percent, the merest trace of moisture reduces the amount of decomposition to 0.1 percent. Neither formic acid nor formaldehyde is formed and the water undergoes no change. Coehn and Tramm³ find that presence of water vapor has no apparent effect on the rate of combination of carbon monoxide and oxygen under the influence of ultra-violet light. This looks as though the water vapor acted merely as a screen.

The photochemical formation of phosgene has been studied by Bodenstein⁴. "The chlorine used contained 0.08 per cent oxygen and a trace of water. Carbon monoxide was made by the reaction of sulfuric acid and formic acid, and was freed from oxygen, carbon dioxide, and water. The results with various mixtures of carbon monoxide and chlorine are very complicated, and are influenced by the moisture present. Experiments on

¹ J. Chem. Soc., 89, 22 (1896); 91, 942 (1907); Ellis and Wells: "The Chemical Action of Ultraviolet Rays," 111 (1925).

² Z. physik. Chem., 91, 347 (1916).

³ Ber., 54, 1148 (1921).

⁴ Rec. Trav. chim., 41, 585 (1922); Ellis and Wells: "The Chemical Action of Ultraviolet Rays," 113 (1925).

the relation between the radiations absorbed and the amount of material transformed show that oxygen retards the reaction and exercises a rather constant effect until just at the end, when its effect is suddenly diminished. Oxygen is sensitized by irradiated chlorine. Carbon dioxide formation is, other things being equal, proportional to the carbon monoxide pressure, increases with the chlorine pressure, but more slowly than directly proportional to it, and decreases with increasing oxygen concentration, but not so rapidly as to be inversely proportional to it. The sensitized reaction also shows a large Draper effect.

"Coehn and Becker¹ find that when carbonyl chloride is passed through a quartz tube at the ordinary temperature, and at the same time submitted to the action of rays from a quartz mercury lamp, it is partly decomposed into carbon monoxide and chlorine. When 1 cc of carbonyl chloride is passed through the quartz tube (20 centimeters long and 0.5 centimeters in diameter) per minute, the amount of decomposition is 3.3-4 percent. The effect is chiefly due to the short ultraviolet rays, since the use of tubes of uviol glass, which are transparent only to waves of greater wave-length than $265\mu\mu$ resulted in a degree of decomposition of only 0.46-0.5 per cent. In ordinary glass tubes there is no decomposition. Coehn and Becker remark that in all the cases hitherto, namely, the photochemical equilibria of sulfur trioxide, hydrogen chloride, and carbonyl chloride, the actual equilibrium is affected only by ultraviolet rays. Rays of greater wave length simply act catalytically on the attainment of equilibrium. Wherly² reports that while experiments using ultraviolet for the production of phosgene by the union of carbon dioxide and chlorine have been successfully tried, the disadvantages on a commercial scale are manifest. By far the greater proportion of phosgene is manufactured by passing carbon monoxide and chlorine over platinized asbestos, charcoal or boneblack heated to redness."

The influence of light on the gaseous systems, hydriodic acid, hydrobromic acid, hydrochloric acid, and their components has been investigated by Coehn and Stuckardt³ at room temperature, equilibrium being reached from both sides. The experiments were carried out in quartz glass, uviol glass, and Jena glass. The percentage decomposition of the three acids at equilibrium is as follows:

	Quartz Glass	Uviol Glass	Jena Glass
	220 $\mu\mu$	254 $\mu\mu$	300 $\mu\mu$
Hydriodic acid	92	100	100
Hydrobromic acid	100	20	0
Hydrochloric acid	0.4	0	0

Hydrochloric acid requires ultra-violet light of $220\mu\mu$ for decomposition and even then the rate of change is small. Under similar conditions hydro-

³ Z. physik. Chem., 91, 722 (1916); Eliis and Wells: "The Chemical Action of Ultraviolet Rays," 110 (1925).

bromic acid is decomposed rapidly and completely. Hydriodic acid is decomposed by blue and violet light.

The displacement of the hydrogen-oxygen equilibrium by ultra-violet light or by radium is complicated by the possible formation of ozone or hydrogen peroxide. Dickinson¹ found that "hydrogen and oxygen in contact with mercury combine to form water at 45°C or even at room temperature when illuminated by rays from a quartz mercury arc lamp cooled by a blast of air. This is said to be due to dissociation of the hydrogen molecule by collisions with mercury atoms excited by absorption of the mercury line, 253.7 μ . In absence of any one of the three substances or of the exciting radiation, no reaction takes place." This seems to be a very clear-cut case of an optical sensitizer.

"The equilibrium point of hydrogen chloride in the dark lies practically at the point of complete formation of this compound from its elements. This equilibrium can be brought about in the absence of light by submitting the mixture of hydrogen and chlorine to the catalytic action of charcoal. Coehn and Wassiljew² find that, if pure hydrogen chloride is submitted to the action of ultraviolet rays from a quartz mercury lamp, it is split up to such an extent that, on collecting the gases over a solution of potassium iodide, about two cubic centimeters of hydrogen are produced in a quarter of an hour. The hydrogen chloride was passed through a quartz tube, which was at a distance of about two centimeters from the lamp, the tubing through which the gases were led away from the quartz tube being protected from all light. When the quartz tube was replaced by one made of ordinary glass, or of uviol glass, no decomposition of the hydrogen chloride took place."

When a solution of anthracene is exposed to light, the anthracene polymerizes to dianthracene³, which may or may not crystallize, depending on the concentration. When melted, dianthracene goes back completely to anthracene and it also goes back more slowly at lower temperatures in contact with the solution. This has been studied exclusively⁴, so far as I know, as the balancing of a light reaction against a dark reaction; but of course there must be light of some wave-length which will accelerate the depolymerization of the dianthracene. Luther and Weigert say that the absorption of light by dianthracene solutions is negligible in comparison with that of anthracene solutions; but this has no special significance because it is a question of the absorption of single bands and the statement cannot be true for the dianthracene absorption bands.

Luther⁵ has studied the reversible decomposition of the silver halides by light electrometrically and has shown that the electrical effect of each in-

tensity of light can be duplicated in the dark by a suitable concentration of the halogen in question.

Haldane¹ found that when air containing as much as one percent of carbon monoxide is shaken with blood solution in bright sunlight, no pink color at all could be observed in the solution; yet, when the bottle was taken into the dark, the pink color appeared at once on shaking. This was confirmed by Hartridge² who gives the following data for the displacement of equilibrium caused by light:

Percentage Carbon Monoxide Haemoglobin

Dark	96	Dark	92	Dark	91
Sunlight	42	Electric light	88	Daylight	80
Sunlight	35	Sunlight	40	6" Magnesium	64

Hartridge says that it is almost self-evident that the active rays correspond to one or more of the absorption bands. "Four little glass tubes containing the same mixture of COHb and ferrieyanide were therefore placed in a spectrum projected by a diffraction grating and Nernst lamp; one was placed in the position of each band. On examination, it was found that the solution placed in the ultra violet had changed to methaemoglobin, the other solutions remaining practically unchanged. This showed clearly that the ultra violet rays had been responsible for the action on the COHb and explains the value obtained in the first experiment quoted for the dissociation caused by different light sources. Those sources rich in actinic rays, *i.e.* sunlight, magnesium, etc., cause a big dissociation, while electric light, lamp light, etc., cause very little because of their poorness in these rays."

In a later paper Hartridge and Roughton³ worked with such a mixture of haemoglobin, oxygen, and carbon monoxide, that there was no free haemoglobin. In one experiment at about 0°, the equilibrium was so displaced by light to the oxygen that there was less than one percent carbon monoxide haemoglobin in the light and well over sixty percent when equilibrium was reached in the dark. Curiously enough, oxyhaemoglobin is apparently insensitive to light so far as dissociation is concerned.

Dewar and Jones⁴ have studied the decomposition of liquid iron carbonyl, Fe(CO)₅, by visible light. When dissolved in dry ether or petroleum ether, light causes decomposition to carbon monoxide and to so-called solid iron carbonyl, Fe₂(CO)₉, which separates as reddish-orange hexagonal plates. These crystals are practically insoluble in ether, petroleum ether, and benzene; but are slightly soluble in methylal, acetone, and alcohol, and are much more soluble in pyridine, forming a reddish solution. When liquid iron carbonyl is dissolved in pyridine and exposed to light, the solution gives off carbon monoxide and turns red, but no solid iron carbonyl precipitates unless the solution is very concentrated. This is, of course, what one would expect.

¹ J. Physiology, 20, 504 (1896).

² J. Physiology, 44, 22 (1912).

³ Proc. Roy. Soc., 94B, 336 (1923).

⁴ Proc. Roy. Soc., 76A, 558 (1905); 79A, 68 (1907).

In the light, the iron carbonyl decomposes even against a pressure of 100 atmospheres of carbon monoxide. The reverse reaction takes place very slowly in the dark but goes on even at low pressures.

"The velocity of the reverse reaction, $\text{Fe}_2(\text{CO})_9 + \text{CO} = 2\text{Fe}(\text{CO})_5$, which proceeds in the dark, was studied by using the same tubes that we used for the examination of the direct reaction. The results show that this is an extremely slow reaction at the ordinary temperature. Tube E, above, containing petroleum ether, has a pressure of three atmospheres after three months, so that only 73 percent of the gas had been absorbed by the solid; after eleven months the pressure was still 1.68 atmospheres, so that 92 percent of the products had recombined.

"In line with this is the fact that dissolved, liquid, iron carbonyl decomposes in the light even against a carbon monoxide pressure of one hundred atmospheres, while the reverse reaction takes place in the dark, even at low pressures, though very slowly.

"In order to determine what kind of light was most effective in inducing this decomposition, small tubes containing a ten percent solution of iron pentacarbonyl in ether were exposed in different parts of a solar spectrum and also to sunlight under different coloured screens. It was found that most rapid decomposition occurred in the blue, then green, closely followed by yellow, and lastly red: exposure under red glass produced roughly about one-tenth the amount of solid produced under blue glass in the same time. Exposure of the liquid in quartz tubes to the electric arc causes slow decomposition only, and the acetylene flame is still less active." It is not quite clear why the red light should produce the least decomposition. It is probably a question of effectiveness rather than of absorption.

Solutions of liquid iron carbonyl in nickel carbonyl "are of a much paler yellow colour than solutions of equal concentrations in other solvents. Thus, for example, a ten percent solution of iron carbonyl in ether has just the same intensity of colour as a thirty percent solution in nickel carbonyl. A ten percent solution deposits no solid after exposure to bright sunlight for several weeks; a twenty-five percent solution (by volume) deposits no solid from the liquid, but solid is deposited in the vapour space above the liquid; a fifty percent solution deposits some solid both in the liquid and in the vapour space.

"That no more decomposition occurs in dilute solutions of iron carbonyl in nickel carbonyl is shown by the facts that no gas is evolved from these solutions, and that solid iron carbonyl is only sparingly soluble in nickel carbonyl. The absence of any change is not to be accounted for by the absorption of the active light by the nickel carbonyl, since the iron carbonyl has been shown above to be sensitive to light in the visible part of the spectrum which is not absorbed by nickel carbonyl. This fact was further confirmed by exposing a small tube full of iron carbonyl immersed in liquid nickel carbonyl to light, when decomposition was found to take place rapidly."

Dewar accounts for this by assuming the formation of $\text{FeNi}(\text{CO})_9$, analogous to $\text{Fe}_2(\text{CO})_9$. "A compound of this kind, though unstable in itself

(since the vapour above the solutions contains iron carbonyl and the concentrated solutions deposit some solid), may yet be unacted upon by light. The existence of this compound is rendered probable by the fact that solutions of iron carbonyl in nickel carbonyl have such a pale colour compared to solutions of the same concentration in other solvents."

"When solid iron carbonyl is heated alone, no change takes place below 100°C; at this temperature a solid and a *green* liquid are formed. But if the solid be heated with liquids such as ether, petroleum ether, or toluene, change begins at about 50°C, the solid decomposes and the liquid acquires an intense green colour. The intensity of the green colour is so great that the solutions are almost opaque, even in thin layers; in more dilute solutions the absorption spectrum shows a distinct band in the yellow. These green solutions, on exposure to light, again deposit yellow crystals of the solid carbonyl, and become colourless."

The green compound appears to be iron tetracarbonyl, FeCO_4 , or some polymer of this. The decomposition of diferro-nonacarbonyl in presence of solvents such as toluene and ether is probably to be represented by the equation

"Further evidence in support of this was obtained by carrying out the decomposition in tubes filled with carbon dioxide and fitted with a mercury manometer. No change of pressure was produced by the decomposition. On exposing the tubes, after heating and now containing a green solution, to light, the orange crystals of diferro-monacarbonyl were deposited, showing that during the action of heat iron pentacarbonyl had been formed." The decomposition of iron tetracarbonyl on heating corresponds apparently to the equation

Stobbe¹ has shown that the orange-yellow crystalline powder of triphenylfulgide (A-form), for which he writes the formula

is stable in the dark but changes when exposed to sunlight or to arc light to a light-brown mass which consists at least in part of the B-form (formula not given). If one uses blue and violet rays instead of white light, the product is dark brown and is probably more nearly pure B-form. The B-form goes back slowly in the dark and more rapidly when exposed to red and yellow light to the orange-yellow A-form.

Stobbe² has also studied the effect of light of different wave-lengths on styrene, the cinnamic acids, etc. "The polymerization of styrene, which takes place spontaneously in the dark, can be accelerated considerably by

¹ Z. Elektrochemie, **14**, 474 (1908).

² Z. angew. Chem., **35**, 587 (1922); Ber., **58B**, 2415 (1925).

exposure to sunlight or to the light of the mercury lamp. A hard, glassy mass is obtained, which swells and then dissolves slowly in styrene, benzene, toluene, nitrobenzene, or carbon tetrachloride. On addition of alcohol to any of these solutions there is obtained a precipitate, which is at first slimy but becomes brittle after repeated precipitation of pure metastyrol, a poly-molecular, saturated hydrocarbon, $(C_7H_8)_{2x}$. The glassy mass, which used to be considered as pure metastyrene is a solid solution of the polymer in amounts of monomeric styrene running up to 25%. Pure metastyrene is not obtained by polymerization in the light (or by the other polymerization methods) because there is also a depolymerization under the influence of light. A benzene solution of metastyrene, after exposure to sunlight, contains unsaturated styrene, as can easily be shown. The pure, white, easily powdered, metastyrene changes to the glassy, yellow product on exposure to ultra-violet light. There is therefore an equilibrium $x(C_7H_8) \rightleftharpoons (C_7H_8)_x$, in sunlight, just as there is for the isomerization of the nitrobenzaldehydoxybenzoins and for the stereomerization of the different ethylene derivatives by ultra-violet light as studied by Stoermer.

"Like styrene, p-methoxystyrene, $CH_3OH \cdot C_6H_4 \cdot CH : CH_2$, is converted by sunlight into a polymer $(C_8H_{10}O)_x$ very similar to metastyrene. No polymerization occurs when the monomeric ether is illuminated by the quartz mercury lamp, and the polymerized metoxystyrene is completely depolymerized by the same wave-lengths. The equilibrium $xC_8H_{10} \rightleftharpoons (C_8H_{10})_x$ is therefore very dependent on the wave-length, more of the polymer being formed with longer wave-lengths and more of the monomer with shorter wave-lengths."

Stilbene¹ changes in sunlight to the distilbene (tetraphenyl cyclobutane). The unsaturated monomeric stilbene absorbs the longer ultra-violet rays and is therefore polymerized by sunlight, while the distilbene at the same concentration absorbs only the shorter ultra-violet rays and consequently is depolymerized by the light from the quartz mercury lamp. It is possible to displace the equilibrium very much in either direction by a suitable choice of wave-length.

Rice² finds that "the yellow methyl and ethyl esters of benzoylacrylic acid are transformed in the sunlight into the corresponding stereoisomeric colorless esters. The reverse transformation of the colorless into the yellow esters take place if the former are exposed to the sunlight in solutions containing a trace of iodine or bromine. In a similar manner the yellow methyl and ethyl esters of p-methoxybenzoylacrylic acid on exposure to the sunlight in benzene solution are transformed into the corresponding colorless isomeric esters. The reverse transformation of the colorless into the yellow esters again results when solutions of the colorless solids containing a crystal of iodine are exposed to the sunlight. The yellow methyl and ethyl esters of

p-ethoxy-benzoylacrylic acid isomerize when exposed to the sunlight both as solids and in benzene solution. The unstable, colorless esters thus formed are transformed quantitatively both in the dark and in the sunlight, when in benzene solutions containing a crystal of iodine, into the stable yellow isomers. Hydrochloric acid brings about the same change."

"According to Reimer¹ the products formed by the action of sunlight on methyl benzalpyruvate exposed in the dry condition are a polymeric ester, melting at 154°C., obtained in small quantity, and an oil, probably a mixture of isomers and decomposition products. On exposure in benzene solution, a reaction which in other cases almost invariably gives an isomeric compound, the product of reaction was found to be a polymer, melting at 117°C. Reactions with these two polymeric substances have shown that the higher melting has the structure of the truxillic acid series, while the lower melting one is related to the truxinic acids. The formation of the latter compound may be explained on the assumption that in solution isomerization had taken place and that the isomeric ester had polymerized. The reaction is an unusual one as but few cases of polymerization of this type of substance in solution have been described.²

"A comparison of this ester, I, with that of benzoylacrylic acid, II,

I

II

is of interest. The system of 'conjugated double linkages' in the two is the same but stands in a different relation to the phenyl and the carboxyl groups. The products obtained from I are polymers, while on exposure of II to the sunlight no polymers are formed but isomerization takes place with the greatest ease. Whether the difference in reaction of these two substances is due to difference in the chemical effect of the neighboring groups on the unsaturated part of the molecule or to a difference in the physical state of the compounds during exposure is still to be determined.

"When specimens of cinnamic acid, melting point 42°, obtained from the acids, melting points 68° and 58°, are exposed to bright daylight during two years, the resulting product consisted of unchanged acid and β -truxillic acid³; but when samples having the melting points 42°, 58°, and 68° were exposed in quartz tubes to direct sunlight which was sufficiently powerful to cause temporary fusion, with consequent isomerization, the product consisted chiefly of α -truxillic acid with little β -truxillic acid and small quantities of trans-cinnamic acid and benzoic acid. The light reactions of cis- and trans-cinnamic acid have been further studied by Stobbe and Steinberger⁴. They find, as did de Jong,⁵ that exposure of cis-cinnamic acid to sunlight gives

⁵ Chem. Abs., **16**, 2683 (1922).

besides the expected β -truxinic acid *trans*-cinnamic acid and α -truxillic acid. Exposure for 96 hours of the liquid melt of *cis*-cinnamic acid to the rays of a quartz-mercury lamp produced extensive isomerization into *trans*-cinnamic acid, but neither β -truxinic nor α -truxillic is formed, the melt thus behaving like benzene or methyl alcohol solutions. It may be said in general that irradiation of the cinnamic acids in the liquid state (solution or melt) produces isomerization but no polymerization. The chief action is ascribed to rays from 270 to 320 μ although the shorter and the longer rays are also not without influence

"The isomerization reaction proceeds in the same way in both the mercury arc rays and in sunlight, but the yield of dimers is very different. Taking each day of exposure as equal to seven hours, *cis*-cinnamic acid after 200 hours in the mercury arc ray gives 4.4 per cent dimers, and after 196 hours in the sunlight 71.0 per cent. For *trans*-cinnamic acid the values are 2 per cent after 364 hours in the mercury arc ray and 85.7 per cent after 161 hours in the sunlight. Long ultra-violet rays favor polymerization, while the shorter rays hinder it, and exert a depolymerizing action on the truxinic and truxillic acids. Comparison of these sunlight experiments with those of de Jong¹ and of Stoermer² shows that *cis*-cinnamic acid yields β -truxinic acid always, and generally in predominant amount, but that, especially on long illumination, there is also isomerization into *trans*-cinnamic acid, and subsequent polymerization to α -truxillic acid. *Trans*-cinnamic acid, on the other hand, is almost exclusively polymerized to α -truxillic acid; only on long illumination are there formed relatively small amounts of β -truxinic acid, accompanied by considerable resinification.

"Experiments with mixtures of equal parts of *cis*- and *trans*-cinnamic acids show that the *trans*-cinnamic acid mixed with the *cis*- form produces no increase of β -truxinic, and that therefore, contrary to de Jong's belief, α -truxinic acid is formed only from two molecules of *cis*-cinnamic acid. In agreement with Stoermer and Scholtz³, Stobbe and Steinberger conclude that β -truxinic acid has a meso and not a racemic structure. Experiments by Stobbe and Lehfeltd have shown that the β -arylacrylic acids, including *trans*-cinnamic acid, are dimerized and autoxidized to benzaldehyde, both in the solid state and in aqueous suspension. Both processes are accelerated by a few drops of hydrochloric acid, the oxidation to a greater extent than the dimerization, and on long illumination the yield of α -truxillic acid diminishes and that of benzaldehyde increases. *Cis*-cinnamic acid behaves similarly, the yield of β -truxinic acid on long irradiation, especially in the presence of hydrochloric acid, decreasing as the result of the autoxidation of the *cis*-cinnamic acid. Here, too, the formation of β -truxinic acid is independent of the presence of admixed *trans*-cinnamic acid; both isomers polymerize, independently, to their dimers, even in suspension.

³ Chem. Abs., 15, 1888 (1921).

"When the acid freshly prepared from the sodium salt of *trans*-cinnamic acid is illuminated in sunlight in hydrochloric acid suspension, it unexpectedly yields only β -truxinic acid and no α -truxillic acid.

"In connection with the stereoisomers of substituted ethylene Stoermer¹ states that the conversion of the labile into the stable modification by the action of light, particularly in the presence of a halogen, is not uncommon. The converse change, produced by light alone, has been remarked in very few cases. Perkin has noted the conversion of methylcoumarinic acid into methylcoumaric acid by sunlight, but Stoermer finds that in the coumaric acid series the tendency is the other way, the stable form changing to the labile under the influence of ultra-violet rays. Thus Perkin's change occurs only to the extent of 25 per cent, whereas coumaric acid yields 75 per cent of coumarin, methylcoumaric acid yields 75 per cent of methylcoumarinic acid, ethylcoumaric acid yields ethylcoumarinic acid quantitatively, and acetyl-coumaric acid is also quantitatively changed to acetylcoumarinic acid. That the changes are caused by the ultra-violet rays is proved by means of light filters, the interposition of a filter which absorbs ultra-violet between the lamp and the solution preventing any change of the stable to the labile modification. Hence the less fusible stable forms of stereoisomeric compounds can be changed directly, under definite conditions, into the more reactive labile modifications if energy is supplied by ultraviolet rays. Thus the stable form of *o*-anisylcinnamic acid, which could not be changed into the labile modification by Stoermer and Frederici has been converted to the extent of 50 per cent by using a more intense radiation. In the case of stereoisomeric α -alkylated acids, the conversion of the stable into the labile form is a matter of great difficulty. The case of cinnamic acid is interesting. A benzene solution of ordinary cinnamic acid was exposed for eight days to the light of a uviol lamp, with the result that 25-30 per cent of Liebermann's isocinnamic acid, melting point 58°, was produced. Allocinnamic acid in benzene is converted into ordinary cinnamic acid under similar conditions. Also fumaric acid changes to maleic acid in eight days, but the conversion of mesaconic acid into citraconic acid is very difficult, these being α -methylated acids. When stilbene in benzene is exposed to ultraviolet for eight days, it is converted to the extent of about 90 per cent into isostilbene, which can be reconverted into stilbene by heating at 170°-180° for one hour, by the vapor of fuming nitric acid in a few minutes, and quantitatively by the exposure to sunlight of its solution in carbon disulfide containing a trace of bromine.

"According to Stoermer, Frederici, Brautigam and Neckel² the stable, less fusible forms of the following compounds are transformed into the labile or more fusible stereoisomers when their benzene or alcoholic solutions are exposed to the action of the ultraviolet rays from a uviol lamp for several days; coumaric acid 75; methylcoumaric acid 75; ethylcoumaric acid over

¹ Ber., 42, 4865 (1909); J. Chem. Soc., 98II, 114 (1910).

² Ber. 44, 637 (1911).

90; propylcoumaric acid 85; methylcoumaramide, 50; ethylcoumaramide 100, propylcoumaramide 95; methyl coumarate; coumarin acetylcoumaric acid over 90; methyl benzoylcoumarate; methyl-*o*-nitro-*o*-methoxycinnamate 80; *o*-nitro-*o* methoxycoumaric acid 40, *p*-methoxycinnamic acid 25; sodium-*o*-chlorocinnamate 10; piperonylacrylic acid 17; maleic acid; *o*-anisylcinnamic acid 35-40; *o*-anisylcinnamide 70; *o*-anisylcinnam-methylamide 36; and the corresponding ethylamide 40; β -*o*-anisyl- α -methylcinnamic acid 5, and the corresponding amide 5; cinnamic isocinnamic acid, melting point 42° , 30-40; phenyl tolyl ketoxime, 40; phenyl anisyl ketoxime. In most cases the reaction is a balanced one, and the number given for each compound represents the percentage for the less fusible compound which has been transformed when equilibrium is established. Crotonic acid is not transformed to any appreciable extent.

"The method is recommended as a suitable one for the preparation of allo-stereoisomers in several cases and also for the detection of spatial isomerism between a pair of compounds. In a few instances the addition of methyl and ethyl alcohol to the unsaturated compounds occurs during the exposure to the ultraviolet but the amounts of such products are usually small. It is suggested that the transformation and the percentage amount transformed depend on the energy differences between the stereoisomers. Sodium fumarate is not transformed, although the corresponding acid yields 30 per cent of maleic acid. These investigations also state that *o*-chlorocinnamic acid, or its sodium salt, when exposed to ultraviolet rays is partly transformed into the allo-acid, $C_9H_7O_2Cl$, but when glacial acetic solutions are used, part of the acid combines with acetic acid, giving a product, $C_{11}H_{11}O_4Cl$, melting point 212° - 213° . When a solution of mesaconic acid is subjected to the action of ultraviolet, water or methyl alcohol appears to combine with the acid. The change from one stereoisomeric form into another under the influence of radiation is frequently observed in the case of compounds containing an ethenoid linkage. In some instances ultraviolet rays produce changes which are the converse of this brought about by ordinary light."

Heilbron and Wilson¹ have shown that "cinnamaldehyde-semicarbazone exhibits a type of phototropy which is the converse of that ordinarily observed. When first prepared, it is colorless, and, if immediately placed in the dark, undergoes no change of color. If, however, the semi-carbazone is exposed to diffused sunlight for some hours, although no visible effect is noticeable, on now placing it in the dark, a yellow color develops on the exposed surfaces, which again disappears on reexposure to light. This phenomenon, which is designated as *reversed* photography, has been further studied by Heilbron, Hudson and Huish².

"The methoxycinnamaldehyde-semicarbazones and -phenylsemicarbazones all crystallize from solution as colorless substances, and, with the exception of *m*-methoxycinnamaldehyde-diphenylsemicarbazone which is

¹ J. Chem. Soc. 105, 2892 (1914); Ellis and Wells: "The Chemical Action of Ultraviolet Rays," 130 (1925).

² J. Chem. Soc. 123, 2273 (1923).

insensitive to either sunlight or ultraviolet, all exhibit reversed phototropic properties. On the other hand, the thiosemicarbazone derivatives, which may be expected to be quite similar in character, exhibit only *direct* phototropy, becoming yellow in diffused sunlight and not reverting to the colorless modification on removal from the source of light. A series of experiments has been carried out with the view of obtaining evidence of phototropic change in solution, and for this purpose solutions of the intensely phototropic o-methoxycinnam-aldehyde-thiosemicarbazone in various solvents were exposed for lengthy periods to sunlight. In no case, however, was there the slightest indication of the production of any color in the solution and it may thus be reasonably concluded that phototropy is essentially a characteristic of the solid state.

"The phenomenon of thermotropy is very strikingly manifested by the semicarbazones exhibiting reversed phototropy. So long as any of these remains unactivated by light, rise in temperature produces no color change. On the other hand, after exposure to sunlight, in certain cases even for so short a period as five minutes, the colorless activated substance becomes yellow almost immediately when placed in a steam-oven.

"It will be seen that in a reversed phototropic change the first effect must be one involving the absorption of a certain number of energy quanta, whereby the molecule is transformed from its inactive, colorless phase (A) into an *active* colorless variety (A'). This latter form is in turn transformed into the colored modification (B), phototropic equilibrium being established between the latter two phases:

Stobbe has shown that in the case of the fulgides¹ the active wave-lengths involved in the bringing about of *direct* phototropic change are those which the substance itself absorbs. As indicated below, this applies equally in the present series. An ordinary photographic plate was fixed, washed, and, when almost dry, dusted over with colorless, inactive cinnamaldehyde-semicarbazone. The plate was then placed in the spectrograph and exposed for about two hours, an iron arc being used as source of radiation. On examining the semi-carbazone, no visible change was detected, but after leaving the plate

¹ J. Chem. Soc., 123, 2273 (1923).

over night, a narrow, yellow band was clearly indicated at $280\text{ }\mu\mu$, this being the characteristic ultraviolet frequency of the substance.

"In order to determine whether energy is emitted during the transformation in the dark of the active, colorless into the colored form, a photographic plate covered with cinnamaldehyde-phenylsemicarbazone was activated in strong light and then placed in the dark in contact with an undeveloped plate. After being left over night, during which time the phenylsemicarbazone had become yellow, the upper plate was developed, but no mark whatsoever could be detected on it.

"Heilbron, Hudson and Huish believe that a phototropic change simply represents an intermediate stage of an irreversible chemical reaction. The active phases of higher energy content which are similar to Baly's activated molecules¹ would tend either to lose energy and again pass into the inactive phase (recrystallization effect), or, on the other hand, to undergo complete chemical change with formation of a new substance. Thus Stobbe² has found with the fulgides, that, when the phototropic change is frequently repeated, the difference of color between the two forms becomes gradually less, the phototropic process giving place to a non-reversible chemical reaction in which a substance of different constitution is produced. Similarly, Halban and Geigel³ have shown that, in the case of tetrabenzoyl ethylene, an irreversible chemical change rapidly follows the primary phototropic process.

"The phototrophy of other substances has also been studied by Stobbe.⁴ The zone of stimulation for colorless β -tetrachloro- α -ketonaphthalene lies in the ultraviolet, while the reverse change is caused by yellowish-green or yellowish rays. Red and blue rays have no action.⁵

"Phenylbenzylidenehydrazine, which forms light yellow crystals or a white powder, becomes red on exposure to violet or ultraviolet rays, becoming again colorless when exposed to yellow or green light. Phenylanisylidene- and phenylcuminyldienhydrazines behave in the same manner, as do also osazones of the benzil series.⁶ Tetraphenyldihydrotriazine⁷ and ethyl oxalisobutyrate⁸ have also been observed to exhibit phototropy."

Kailan⁹ has determined the equilibrium which exists between fumaric and maleic acids and also the velocity of transformation in either direction. "The transformation was carried out in aqueous solutions of the acids of 0.084 N and these were subjected to the action of a quartz-mercury lamp in vessels of glass and of quartz. In the solid condition fumaric acid is not converted into maleic acid by ultraviolet, while maleic acid is converted into fumaric acid only to the very slightest extent. In aqueous solution whether the solu-

tion was contained in glass or in quartz vessels, an equilibrium between the two acids could be reached from either side. The equilibrium was displaced somewhat toward the maleic acid side with increasing concentration. Thus at 45°-50° with N/10 solution the equilibrium mixture contained 75 per cent of maleic acid and in 4N/10 solution 79 per cent of maleic acid. The velocity of transformation was much greater in quartz vessels than in glass vessels, while the position of the equilibrium is uninfluenced. Maleic acid is formed when a mixture of benzoic and formic acids is exposed either to the action of ultraviolet or to the penetrating radium rays.¹ Formic acid is decomposed by the action of radiation from a quartz-mercury vapor lamp, and benzoic acid is converted into formic acid in the same manner."

A detailed study of the photolysis of acetaldehyde has been made by Berthelot and Gaudechon,² who state that "ultraviolet rays of long wavelength do not convert the aldehyde into acetic acid in the absence of oxygen. Under the influence of medium and extreme rays oxidation takes place even in the absence of oxygen, a portion of the aldehyde being converted into acetic acid. The amount of acid produced is far greater when the aldehyde is in the form of vapor than when it is liquid. With rays of wave-length 250 $\mu\mu$ polymerization is rapid, both para and meta acetaldehyde being formed. No resinification results from the action of long ultraviolet rays, and it is only slowly produced by the medium and extreme rays. The presence of water checks polymerization and resinification, but favors acidification, formic acid being produced in this case and in amount almost equal to that of the acetic acid. Of three compounds studied, viz.: acetaldehyde, ethyl alcohol, and acetic acid,³ only acetaldehyde is decomposed by sunlight (wave-length greater than 300 $\mu\mu$). Rays from a mercury lamp screened by thin glass which absorbs all rays of wave-length less than 300 $\mu\mu$ decompose acetaldehyde in accordance with the equation $\text{CH}_3 \cdot \text{CHO} = \text{CO} + \text{CH}_4$. Frequently the proportion of methane to carbon monoxide actually found is somewhat less than corresponds to this equation, for the light causes polymerization of some of the aldehyde to paraldehyde which is then photolyzed to carbon monoxide and ethane or more complex substances. These latter reactions are most readily produced by the extreme ultraviolet rays. Direct rays from a mercury lamp, without any interposed screen, photolyze not only acetaldehyde but ethyl alcohol and acetic acid. Ethyl alcohol is decomposed primarily into acetaldehyde and hydrogen,⁴ but usually some carbon monoxide and ethane are formed by the further decomposition of the aldehyde. By the photolysis of acetic acid a gas was obtained which contained 44 per cent of carbon dioxide, 17 per cent of carbon monoxide and 39 per cent of combustible gases.⁵ These results relate to photolysis in absence of air. In presence of water the reactions take substantially the same course, but there is a tendency toward the formation of acid products."

Luther and Plotnikow¹ point out that quite a number of photochemical reactions, which people have called reversible, are not so in fact. A simple case of this is the iron oxalate developer, which probably few people can remember having used. "The red solution of ferrous oxalate becomes muddy and then green on standing in the dark, because the ferrous oxalate is oxidized to ferric oxalate by the oxygen of the air. If this green solution is exposed to a sufficiently intense light, it becomes red again because the light converts ferric oxalate into ferrous oxalate and carbon dioxide. If one only considers the color change, one might put this in the class of truly reversible reactions. This is of course not the case because the reversible reaction is necessarily tied up with an irreversible one, the oxidation of oxalic acid by the oxygen of the air. The color change from red to green and back again cannot be repeated indefinitely. It will stop as soon as either the oxygen or the oxalic acid is used up. Some years ago Dr. Kuntze-Fechner, working in this laboratory, found that with a number of the so-called phototropic solids the apparently reversible color change was accompanied by an irreversible formation of a stable isomer." This actually occurs with the triphenylfulgide² to which reference has already been made. The orange and brown modifications are identical in composition and give the same thing when dissolved. They differ only in the solid state. If the phototropic change is repeated frequently, the difference between the shades of the two forms becomes less, owing to the occurrence of a chemical change which results finally in the complete conversion of the fulgide into a new substance, the photo-anhydride.

Many people do not like to say there has been a displacement of equilibrium by a catalyst when alcohol decomposes to acetaldehyde and hydrogen with nickel and to ethylene and water with alumina, because the second reaction is possibly not reversible. We could get round this by postulating that the nature of the catalyst determines the nature of the change from one stationary state to other stationary states.

Following this line of thought, I should like to mention a few cases which do not at present constitute a displacement of equilibrium in the strict sense of the word. Berthelot and Gaudechon³ found that ultraviolet light causes partial polymerization of acetylene to a yellow solid, presumably the same that the newspapers made so much of an outcry over when Coolidge obtained it by the action of his improved cathode ray tube. Under similar exposure ethylene polymerizes to a liquid boiling above 100°. A mixture of ethylene and acetylene gave a mixture of the polymerization products and no interaction between ethylene and acetylene.

Acrylic acid⁴ in a sealed glass tube is apparently not affected appreciably by diffused light. Sunlight converts it slowly into a solid polymer. When sealed in a quartz tube and exposed to ultraviolet light, it polymerizes rapidly to the same solid.

Quite extraordinary are the polymerization products¹ of vinyl chloride, $\text{CH}_2\text{:CHCl}$, and vinyl bromide, $\text{CH}_2\text{:CHBr}$. "The chloride forms an amorphous, insoluble substance of specific gravity 1.406, which melts above 130°C . with decomposition.² The polymerized bromide is likewise insoluble in water, alcohol or ether, and has a specific gravity of 2.075. The polymer begins to decompose at $125^\circ\text{--}130^\circ\text{C}$. It is stated by Plotnikov³ that a solution of vinyl chloride, as distinguished from ethylene, polymerizes to a substance thought to be $(\text{CH}_2\text{:CHCl})^{16}$ in the extreme ultraviolet of a mercury lamp. Sunlight is effective only in the presence of catalyzers, such as the salts of manganese, cobalt, nickel, copper and vanadium, and is most active with uranyl salts. The white precipitate obtained dissolves in many organic solvents to form colloidal solutions varying in character from paste to solid. Details of the production of useful products by the polymerization of vinyl esters when employing the mercury vapor lamp are given by Klatte and Tollett.⁴ The polymerization can be accelerated by catalyzers, benzoyl peroxide, ozonides, and anhydrides of organic acids in conjunction with an agent giving off oxygen (perborates, percarbonates, silver oxide, etc., being mentioned for the purpose).

"The polymerization products, which form more or less rapidly in accordance with the intensity of illumination and the temperature, are solid, colorless, and transparent celluloid-like masses which are odorless and can be turned, cut, planed, and otherwise manipulated to form various articles. These solids rendered plastic in hot water can be molded and, upon cooling, the material becomes hard again. Chlorinated esters may be polymerized by heat and light as a two-stage operation in the following manner: 1 kilogram of vinyl chloroacetate is mixed with from 0.5 to 1 gram of benzoyl peroxide and carefully heated in a large vessel provided with a reflux condenser. At from 60° to 100° polymerization takes place, while the temperature rises rapidly. At this time care should be taken to cool the reaction vessel. The violence of the reaction may be modified by diluting the reaction liquid with an indifferent solvent; for instance, in the present example, about 300 grams of chlorobenzene can be used. The reaction product is a viscous syrupy mass which can be further treated by exposing to light without a diluent, solid masses being obtained as the remaining unaltered vinyl ester polymerizes. The syrupy solution or a solution made from the completely polymerized ester may be used as a lacquer or other coating compound. When allowed to dry in thin layers, colorless films of a celluloid-like nature are said to be obtained. Vinyl chloride may be polymerized by ultraviolet rays, but the product derived is not as satisfactory as that obtained from the esters mentioned. According to Kuhl⁵ the polymerization of vinyl esters (vinyl acetate or vinyl chloroacetate) by ultraviolet light yields solid masses, which may serve as substitutes for celluloid and which are fireproof and odorless. The poly-

merization is assisted by catalytic agents (organic peroxides) to give thick syrups which on illumination give solid masses having valuable properties.

"The polymerization of vinyl chloride in the extreme ultraviolet has been utilized by Plotnikow¹ to make "synthetic rubber." He exposed a 2.5 per cent solution of vinyl chloride in methyl alcohol to ultraviolet radiation. Carbon tetrachloride was found to accelerate the transformation.

"As a representative of the β - γ , ethylenic acids, γ phenylvinylacetic acid in benzene solution was exposed to ultraviolet rays by Stoermer and Stockmann.² The acid resinified to a considerable degree. Although the allo-form could not be obtained in crystalline form, the crystalline allo-amide was isolated and converted by raying into the stable variety. Ostromuislen-ski³ obtained by the polymerization of vinyl bromide a material which he termed caouprene bromide. This exists in three forms, α , β , and γ . When the α and β forms are submitted to the action of ultraviolet the γ form is yielded. Stobbe and Toepfer⁴ report that p-vinylanisole is polymerized when placed in glass tubes in direct sunlight, the extent of reaction being about the same after four days' exposure as after four hours at 100° C. in the dark. If a little of the polymeric form is added, the polymerization proceeds as far in one day as it does in four days with the pure substance. When p-vinylanisole in quartz tubes at 30° C. is alternately irradiated by a quartz mercury lamp and kept dark, polymerization appears not to proceed during the period of raying, but during the following periods of darkness. It is concluded that rays of wave-length longer than 330 $\mu\mu$ cause polymerization while rays of shorter wave-length reverse the reaction."

If we interpret displacement of equilibrium in the broad sense of passing from one stationary state to another, we shall include all photochemical decompositions. It is not desirable to do this at the present time.

Summary

So long as we confine ourselves to reversible equilibrium the theory of the displacement of equilibrium by light is as simple as can be. The conditions must be such that a photochemical change takes place and that the rate of photochemical change shall be greater than the sum of the rates of the reverse reaction in the dark and in the light. Since one can usually increase the rate of the reverse reaction in the dark considerably relatively to the rates of the photochemical reactions by raising the temperature, the amount of the displacement of equilibrium by any given light usually decreases with rising temperature.

RELATION BETWEEN PHOTO-CHEMICAL AND IONIZATION REACTIONS

BY S. C. LIND

Both of these classes of reactions may be profitably considered from the standpoint of their quantum relations, the former through the Einstein Equivalence Law, the latter through the principle of ionic-chemical equivalence. The primary step of activation may be regarded in each case as involving a single electron in a single molecule. While the activity of an ion is due to the complete removal of an electron from the molecule acted on, photo-chemical activation is attributed to the shift of an electron from the normal orbit to one of higher energy, or to a kind of internal ionisation. The energy necessary to ionize is greater than that to excite, accordingly the latent energy possessed by an ion is greater than that of the excited molecule, and one should expect the activity of ions to be more universal and possibly to extend to reactions requiring more energy. Nevertheless the energy of excitation is quite sufficient to accomplish many vigorous and also quite unusual reactions.

Qualitatively one does find some differences of the character just indicated, though perhaps to a less degree than might be expected. Quantitatively, the question presents itself in the form of comparing the yields per quantum and per ion.

As is well known, the yield per light quantum often exceeds the direct prediction of Einstein's law by very large amounts.¹ It has long been stressed by Bodenstein, Stark, Warburg and others that this does not constitute a ground for the rejection of the the Einstein law but is merely an indication that the law holds for the primary step which may be and often is then followed by a chain or cyclical reaction series which may multiply the quantum yield by a large number of cycles. Until recently this assumption had not been tested experimentally, as there was no independent means of determining the primary action or number of cycles.

Using two different activating agencies for the $\text{H}_2 + \text{Cl}_2$ reaction, light for the production of quanta and α radiation for the generation of ions, Porter, Bardwell and Lind² recently showed that the quantity of HCl formed varies through a wide range of sensitivities of reaction mixture but always in exactly the same degree for the two forms of radiation, hence the length of reaction chains seems to be identical for both. In absolute terms it was found that each chlorine ion (positive or negative) produced about *twice* as many HCl molecules as one light quantum³ (blue). This result shows that, tracing back

¹ A. J. Allmand: Trans. Faraday Soc., 21, 446 (1926).

² J. Am. Chem. Soc., 48, 2603 (1926).

³ There was even some indication that this difference at 25° might disappear at 100°, though this requires further substantiation.

to the primary unit from two independent directions, its reality is established in terms of reaction yield, thus answering one of the most persistent criticisms of the Einstein Law.

Unfortunately there is not a large number of reactions that have been examined for both photo- and ionic activation in the same systems and none, perhaps, where the identity of conditions was insured to the same degree as in $H_2 - Cl_2$ reaction.

One is therefore not justified in concluding that the parallelism holds for all or even a large number of reactions. This reaction ($H_2 + Cl_2$) is the only one known where anything approaching so large a yield per ion ($+ M_{HCL}/N = 5 \times 10^5$) has been found. The next largest, that of polymerization of acetylene ($-M_{C_2H_2}/N = 20$) is much smaller and has none of the characteristics of a chain mechanism, since it remains constant under all circumstances even in the presence of inhibitive oxygen¹ and also of positive catalytic gases.² Unlike the ion yield, departure of quantum yield ($M/h\nu$) from the Einstein equivalence seem to be the rule rather than the exception.

Taylor³ has suggested that the long chain mechanism of photo-reactions is due to the potency not only of free atoms but of free radicals (like C_2H_5- and $CHO-$) in maintaining reaction chains. The reactions which Marshall⁴ has examined, however, thought to be long-chained, have proved to be rather short with a yield of the same general order as the M/N yield of the ionic reactions; for example:

for $H_2 + CO$: $-M_{(H_2 + CO)}/h\nu = 4.8$; $-M_{(H_2 + CO)}/N = 3.2$.⁵

For $H_2 + O_2$: $+M_{H_2O_2}/h\nu = 6.6$;⁴ $+M_{H_2O}/N = 4$; for $2HBr = H_2 + Br_2^6$ $-M_{HBr}/h\nu = 2$; $-M_{HBr}/N^7 = 2.6$; for NH_3 decomposition $-M_{NH_3}/h\nu^8 = 0.25$; $-M_{NH_3}/N^9 = 0.8$.

Other points of similarity exist with respect to the decomposition of NH_3 by light and by α particles—for example, a positive temperature coefficient due to an increase of quantum yield¹⁰: $-M_{NH_3}/h\nu = 0.4$ at 20° , but 3.3 at 500° ; while $-M_{NH_3}/N = 0.8$ at 18° but 2.5 at 355° .¹¹

It is not only the energy relations which strike one in the photo- and radio-chemical actions but—the fact that reactions ordinarily requiring high temperatures are brought about readily at room temperature. This is no longer surprising when the energy expense per unit of action is considered.

¹¹ K. Kuhn: Compt. rend., 117, 956; 178, 708 (1924).

But the directness is surprising with which certain final products are obtained which would usually be possible only through several successive steps; for example, the direct addition¹ of $\text{H}_2 + \text{O}_2$ to form H_2O_2 or the splitting out of H_2 from two hydrocarbons under ionizing influence to give the hydrocarbon with double the number of C atoms as: $2\text{C}_2\text{H}_6 = \text{C}_4\text{H}_{10} + \text{H}_2^2$.

In this same connection it is interesting that while ammonia shows no such tendency as do the hydrocarbons to double up with elimination of hydrogen under ionizing influence, Taylor³ has found evidence of the formation of hydrazine when ammonia is acted on by resonated Hg atoms.

On the whole there are some great similarities, but no less striking differences between the photo- and ion reaction mechanisms. In ionisation, clustering seems to be the first step. Theoretically this would be expected from the strong electrostatic attraction exerted by the free charge. It may be this force which prevents disruption and shattering of the molecule under ionizing forces, which is assumed to occur under collisions with photo-sensitized mercury atoms.⁴ Clustering thus prevents chain mechanism and by the same argument we conclude that the chain mechanism does not begin in the $\text{H}_2 + \text{Cl}_2^+$ (or Cl_2^-) reaction until electrical neutrality has been re-established.⁵

A new and striking case in point may be gained by comparing the recent results of McDonald⁶ on the decomposition of N_2O by ultraviolet light ($\lambda 1860$ to 1990 \AA.U.) with the earlier ones of Wourtsel under α radiation. McDonald finds the quantum yield $-\text{M}_{\text{N}_2\text{O}}/h\nu = 3.9$, while Wurtzel⁷ found $-\text{M}_{\text{N}_2\text{O}}/\text{N} = 1.74$ to 2.55 . If we use the Mund Equation⁸ for calculating ionization (N), we are probably justified in multiplying Wourtsel's yield by 1.55 , which brings it into close agreement with McDonald's quantum yield. The fact that both are in accord with the stoichiometric formula $4 \text{ N}_2\text{O} = 3 \text{ N}_2 + 2 \text{ NO}_2$ (or $2 \text{ NO} + \text{O}_2$) must suggest "stoichiometric" clustering⁹ about an ionized N_2O molecule on the one hand and an excited one on the other, which is a much more direct mechanism than the steps that have been proposed. Of course at ordinary pressure the excited molecule will exist long enough for the successive clustering collisions to occur. It is to be emphasized that a *quadruple* collision is not necessary.

From this review, it appears that there is great need for the examination of more reactions by both methods of activation, ionization and excitation, under identical conditions before it can be stated how far the parallel between $\text{M}/h\nu$ and M/N yields will extend.

LATENT HEAT OF VAPORISATION AS A FUNCTION OF TEMPERATURE

BY RAMSEY M. WINTER

It has been shown by Sugden¹ that for a number of non-associated liquids the classical van der Waals expression for the variation of surface tension with temperature may be written,

$$(1) \quad \gamma = \gamma_0 (1 - T_r)^{6/5}$$

where γ is the surface tension, γ_0 an empirical constant not explicitly derived from the critical data as in the original expression, and T_r the reduced temperature. It has also been demonstrated by Sugden² that for a large number of liquids the difference in density between the liquid and its saturated vapour may be predicted with a high degree of accuracy and over a wide range of temperature by an equation of similar form, namely,

$$(2) \quad D - d = D_0 (1 - T_r)^{3/10}$$

where D and d are the densities of the liquid and vapour respectively. The fact that these two physical properties are thus predictable in terms of only two specific constants one of which is the critical temperature, led the writer to examine the variation with temperature of the latent heat of vaporisation. It was found that this too can be expressed by an equation of the same type,

$$(3) \quad \lambda = \lambda_0 (1 - T_r)^{2/5}.$$

In this expression λ is the *total* latent heat of vaporisation, (not the internal latent heat as in the well known formula of Mills connecting latent heats and densities), and λ_0 is a constant to be determined. While this relation like equations (1) and (2) must for the present be regarded as purely empirical, it appears to be quite generally true; its value lies in its application to thermodynamic calculation, in the close connection between latent heat and vapour pressure, and in the development of an independent series of atomic and structural constants analogous to the parachor³ thus opening up a fresh line of attack on problems of chemical structure. It is not proposed to discuss these applications here but to reserve them for separate treatment.

For the purpose of verifying equation (3), great use has been made of the data published by Mills in a long series of papers.⁴ The latent heats of vaporisation of thirty-eight⁵ liquids at temperatures ranging from 0°C. up to the critical temperature were calculated by him from Young's vapour pressure and density data by means of the Clapeyron equation,

¹ J. Chem. Soc., 125, 32 (1924).

² J. Chem. Soc., 129, 1780 (1926).

³ Sugden and co-workers: J. Chem. Soc., 125, 1177 (1924); 127, 1525, 1868, 2517; 128, 139 (1925).

⁴ J. Phys. Chem., 6, 209 (1902); 8, 383, 594 (1904); 9, 402 (1905); 10, 1 (1906); 11, 132, 594 (1907); 13, 512 (1909).

⁵ J. Am. Chem. Soc., 31, 1099 (1909).

$$(4) \quad \lambda = T \frac{dp}{dT} (V - v).$$

To facilitate calculation he expressed the vapour pressure data by means of a Biot formula and computed values of the differential coefficient analytically. The fact that any empirical equation is less reliable near the limits of its range, together with the observation by Mills that the variation of vapour pressure in the vicinity of the critical temperature cannot be accurately expressed by means of a formula of the Biot type, led him to conclude¹ that, "The values at 0° and in the immediate neighbourhood of the critical temperature must, therefore, be excluded from consideration because of errors introduced by the calculation." With this limitation he claimed for his calculated latent heats an accuracy of at least two percent, and stated that "usually the error is less than 1 percent."

Expressing equation (3) in the form

$$(5) \quad \lambda^{5/2}_0 = \lambda^{5/2} (1 - T_r) = \lambda_0^{5/2} - \lambda_0^{5/2} T/T_c$$

it is evident that $\lambda^{5/2}$ should be a linear function of the temperature. This has been tested with Mills' data and found to hold, except for those regions where the data themselves are inaccurate. The values of λ_0 and of T_c for twenty-two liquids have been obtained by plotting $\lambda^{5/2}$ against temperature, and by taking the best straight line through the points. They are set out in Table I, the observed critical temperatures being inserted for comparison.

¹ J. Am. Chem. Soc., 31, 1103 (1909).

The results for ethane are obtained from the observations of Parker,¹ while those for mercury are based on the vapour pressure measurements of Smith and Menzies.² In the latter case since the vapour densities at higher temperatures are unknown, the "observed" latent heats had to be calculated by means of the approximate form of the Clapeyron equation,

$$(6) \quad \lambda = RT^2 \frac{d \log p}{dT}.$$

As this is accurate only when the specific volume of the liquid is negligible beside that of the vapour, the applicability of equation (3) to mercury could not be tested above 650°K.

The accuracy with which the experimental data can be reproduced from the smoothed values of the constants by means of equation (3) has been tested and the results given in Table II. It will be seen that for the range over which the "observed" data are reliable the agreement is good, the great-

est conformity being found in the case of propyl acetate stannic chloride and mercury. Except at the ends of the temperature range the latent heats computed by equation (3) rarely differ by more than half a calorie per gram from the "observed" values, and the differences are usually erratic in sign.

It is of interest to note that the relation (3) holds approximately at higher temperatures even for associated liquids such as methyl and ethyl alcohols. The departure from conformity to the relation with falling temperature probably corresponds to the progressive association of the liquid.

By eliminating the quantity $(1 - T_r)$ between equations (1) (2) and (3) two interesting relations are obtained connecting the latent heat of vaporisation, the liquid and vapour densities, and the surface tension. These relations are,

$$(7) \quad \gamma = \text{const.} \times \lambda^3$$

$$\text{and (8)} \quad \lambda = \text{const.} \times (D - d)^{4/3}.$$

In conclusion I should like to express my thanks to Dr. S. Sugden of Birkbeck College, London, for his lively interest, encouragement, and suggestions in connection with this paper.

THE SURFACE TENSION AND THE STRUCTURE OF THE SURFACE OF AQUEOUS AMMONIA SOLUTIONS¹

BY OSCAR KNEFLER RICE²

The surface tension of ammonia solutions has previously been measured by Domke,³ Pederson,⁴ and Stocker.⁵ Domke used only three solutions, and his measurements were admittedly inaccurate, being done in open capillaries, so that evaporation could not be controlled. As the other two used the oscillating jet method the interpretation of their results is not unambiguous.⁶

The surface tension of aqueous ammonia solutions has therefore been redetermined, and an attempt has been made to interpret the results.

Experimental Methods and Results

In making measurements on ammonia solutions not only does one have to guard against excessive evaporation, but also, and this is apparently more important, against the action of the solution on glass. This latter factor prevents the use of the drop weight method, for in the time required for the formation of a drop the surface tension might be appreciably altered. It also makes inconvenient the use of a cathetometer for the capillary rise method, though the difficulties could probably be overcome. The method actually adopted consisted in the use of a capillary tube of fairly wide bore with a scale behind it. (See Fig. 1). The capillary, C, approximately half a millimeter in diameter was placed at such an angle as to secure an increase in sensitiveness of about five fold. Directly under it at nearly the same angle, was the tube B, which was .464 cm. in diameter. These were connected, as shown in Fig. 1, to a wide tube, A, about 2.5 cm. in diameter, and so fixed that they were absolutely rigid. Scales placed back of B and C enabled one to read the position of the meniscus in each of the tubes, first for distilled

water, then for ammonia solution. From the calibration to be described below, the difference in vertical height of the capillary columns of water and ammonia could then be calculated. The height of the capillary column in the case of water (i.e. the difference of capillary rise in C and B) was determined in a way which will also be described later. Knowing the surface tension of water and the density of the solution it is then possible to calculate the difference in surface tension of water and the given solution of ammonia.

The upper end of the tube B communicated with the reservoir tube, A, to insure equalization of pressure. Also, when in use, the upper part of C was connected by means of a piece of rubber tubing to a side arm on the upper part of A, while A itself was closed with a rubber stopper. Thus evaporation was completely prevented. The rubber tube at the upper part of C was also used to manipulate the liquid in the capillary. When a reading was to be made fresh solution was drawn into the capillary from the wide portion of the tube C, the meniscus was brought up above its position of equilibrium and allowed to fall to rest. In the case of the ammonia solutions the meniscus would begin to climb after about half a minute to a minute, indicating an increase of surface tension, probably due to action on the glass, since long standing to insure equilibrium did not seem to prevent it from occurring. In the case of water irregular movements of the meniscus and slight decreases in surface tension sometimes occurred after varying times. However, the first position of the meniscus seemed to be perfectly reproducible, except occasionally when the meniscus behaved erratically.¹

The tubes (mentioned before but not shown in the figure) at the upper part of the apparatus were arranged to support a couple of spirit levels, which were rigidly sealed to the apparatus, and by means of which the apparatus could always be placed in the proper position.

The whole was placed in a water bath, the temperature of which was read, and taken to be the temperature of the substance measured. The effect of temperature on the readings with water and concentrated ammonia solutions was tested, and it was found that the correction was within the limits of error the same for both. A thermostat was not used, but correction made for the temperature.

The apparatus was frequently cleaned during the course of the experiments with concentrated nitric acid.

Calibration of the apparatus and accuracy of the results.

I. Calibration of the scale on B in terms of vertical height.—Mercury was placed in the lower part of A to cut off B and C, and the height in A of a known volume of water from a pipette was measured by a cathetometer, allowance being made for slight movement of the mercury. Then the mercury was removed and liquid from a pipette allowed to drain in, the difference of readings in B being noted. The cross section of B was known, and after allowance was made for the amount of water which entered B itself the change in vertical height for a given difference of readings in B could be determined. This was done for various parts of the scale. I estimate that there may have been introduced in this way a systematic error of $\frac{1}{2}$ to $\frac{3}{4}$ per cent, and an error of perhaps the same amount which would differ in magnitude and sign for different parts of the scale.

¹ The length of time the solution stood in the apparatus did not seem to influence the results, and solution in A, obtained by tilting the apparatus, had, within experimental error, the same surface tension as that which had been standing in the narrower tube, except on one occasion when the difference was barely outside the usual experimental error.

II. Measurement of the difference of capillary rise in tubes C and B.—First the vertical height of the estimated center of the meniscus in C above the lowest part of the meniscus in A was measured. To this was added .01 cm. to correct for the difference in level A and a tube of very large diameter.¹ The diameter of B being known the calculated capillary rise was subtracted from the above results. I estimate that these operations were attended with a possible error of $\frac{1}{2}$ to $\frac{3}{4}$ per cent.

The above procedure involves the assumption that the shape of the meniscus for water and an ammonia solution are sufficiently alike in the slanting tube B so as not to cause any appreciable error. The lowest portion of the meniscus in B is read in each case, and we assume in effect that the capillary correction is the same in each case. We estimate that the entire capillary correction, if added say to one reading and not to the other, would make an error of about .4 dyne. Now the surface tension of the most concentrated ammonia solution measured is about 22 per cent less than that of water and its density is about 10 per cent less. If its density were also 22 per cent less it would have exactly the same capillary correction as water. In the actual situation it is obvious that the difference in capillary correction will be a very small fraction of .4 dyne.

III. Readings with water in the apparatus.—From time to time during the course of the experiments, for purposes of calibration, and to check up on the alignment of the apparatus when the scales had to be removed and replaced, many readings were made of the simultaneous levels in B and C of pure water. A reading would be taken, some water removed by a dropper, and another reading taken, and so on, down the length of the scales. In this way a plot of the scale readings against the upper scale reading was made, and the best curve drawn through the points. Some readings were also taken by the method used in the case of the ammonia solutions, several readings being taken without changing the amount of water in the apparatus. It is thought that the curve is correct at all points to within .03 or .04 dyne.

In reading the scale at B parallax was avoided by use of another scale placed so that the marks were seen partly through B and partly outside it. When they appeared straight there was no parallax. The scale on C, itself, served to avoid parallax there.

In order to test the accuracy of the apparatus a series of readings in different parts of the scale for a solution of sodium chloride (Kahlbaum's "für Analyse") of concentration 5.00 moles per liter of solution was made, the values of $\Delta\gamma$ (which we shall use to designate the difference, taken as positive, between the surface tension of water and a solution) being as follows: 9.38, 9.35, 9.26, 9.24, 9.30, 9.35, 9.38. The average, 9.32 agrees well with Harkins and McLaughlin's value² of 9.37. An error of 1 per cent. in either of the calibrations I or II, or in both together, if they were in such directions as to add, would cause an error of about .04 dyne in the final result.

A similar series of readings for an ammonia solution of concentration 3.86 moles per liter gave the following values: 6.90, 6.80, 6.76, 6.75, 6.84, 6.72, 6.86.

By making the calculations it is seen that calibrations I and II have approximately equal effects on the accuracy of the final result, and that an error in either I or II which will increase $\Delta\gamma$ in the case of sodium chloride will decrease it in the case of ammonia. An error in either has more effect on the final result in the case of ammonia (causes about 1.5 to 2 times the percentage error in $\Delta\gamma$). Also, the effect of an error in calibration will vary, but not much, for different concentrations of ammonia. The difference in the various cases is caused by the way the density enters the calculations.

On the whole it seems safe to conclude that errors in the calibrations will not introduce an error appreciably greater than 1 per cent in the final $\Delta\gamma$ values for ammonia solutions. Results from an earlier piece of apparatus of slightly different design, which was broken so that the calibration could not be rechecked, show a systematic deviation from the values here given, $\Delta\gamma$

¹ Richards and Coombs: J. Am. Chem. Soc., 37, 1663 (1915).

² Harkins and McLaughlin: J. Am. Chem. Soc., 47, 2085 (1925).

being about 2 per cent. larger. $\Delta\gamma$ values for salt solutions measured in this apparatus, however, are smaller than those of Harkins and McLaughlin as follows: 2.90 M., 0.13 dynes; 2.00 M., 0.07 dynes; 1.00 M., 0.06 dynes.

As to non-systematic errors, we may expect occasional but infrequent errors up to about 0.1 dynes, since in general a given solution was measured at only one part of the scale.

FIG. 2
Difference in Surface Tension of Ammonia
and Water Solutions

Surface tensions were measured on U. S. P. ammonia solutions, and on a C. P. ammonia prepared by passing ammonia gas from a tank into distilled water. This gas was passed through two traps, one containing a small amount of water which quickly became concentrated ammonia solution, and one empty. The latter solution was kept in a Jena glass bottle until diluted just before use, and all measurements on it were made within ten days after it had been prepared.

The concentration of the solutions was determined from the density, ammonia being poured directly from the apparatus into a pycnometer. The table used was that of Runge and Wiernik.¹ The relative density of ammonia solution with respect to water was corrected to 18.50°C., which was close to the temperature at which all the readings were made, and this value used in the calculation of the surface tension.

The final results are given in Table I and plotted in Fig. 2. They do not seem to check the results of previous experimenters.

Adsorption of Ammonia at the Surface

The amount of adsorption is to be calculated from the equation

$$\partial\gamma/\partial n = - \Gamma \partial\bar{F}/\partial n \quad (1)$$

where γ is the surface tension, n the concentration (we shall always use it in moles per liter of solution), \bar{F} the partial free energy of the solute, and Γ is defined by Lewis and Randall² as the amount of solute which must be added to keep the composition of the body of the solution constant when the surface is increased by unity. Since $\bar{F} = RT \log p + \text{const.}$, where p is the partial vapor pressure of ammonia, R the gas constant, and T the absolute temperature³, we may calculate Γ if we know p .

¹ Comey and Hahn: "A Dictionary of Chemical Solubilities," 20 (1921).

² Lewis and Randall: "Thermodynamics," 250 (1923). Γ is called by them n_s .

³ Ammonia vapor is nearly a perfect gas. Landolt-Börnstein: "Tabellen," 269 (1923).

*The surface tension of ammonia solutions is always less than that of water.

†Measured in different piece of apparatus than that described.

As the figure will be of interest later we have plotted $\log_{10} p$ against n in Fig. 3. The values shown by the plain circles are partial pressures by Perman,¹ while the values designated by circles with a tail are from total pressures by Perman² from which have been subtracted partial pressures of water according to Perman, extrapolated where necessary. The crosses are from Wilson's data³ (Wilson's observed total pressures, corrected for slight differences in temperature, minus Wilson's partial pressure of water interpolated), and the X's are from data of Sims,⁴ corrected by using the now known values of the partial pressure of water. All the data are for 20°C., and it is not worth while to correct to 18.5. The agreement between the various sets of data is very poor, but to get a general idea of the situation we use Perman's as his observations are most numerous. From the slopes in Figs. 2 and 3 we have calculated Γ , which is given for several concentrations in Table II. (For small concentrations a plot of p against n was used instead of Fig. 3).

There are other quantities which are more interesting than the quantity Γ defined as above. Suppose we denote by x the distance from the surface

¹ Perman: J. Chem. Soc., 83, 1168 (1903).

² Perman: J. Chem. Soc., 79, 721 (1901).

³ Wilson: Bull. Eng. Expt. Station, Univ. Illinois, 146, 15, 26 (1925).

⁴ Sims: Ann., 118, 347 (1861).

of the solution¹ and by n_x the concentration of ammonia molecules at a point x . Then we can define a quantity u by the equation

$$u = \int_0^\infty u_x dx \quad (2)$$

where $u_x = n_x - n$. Now u will differ² from Γ , for while u is the excess of solute at the surface, and an amount of solute equal to u must be added to the solution to replace it after the surface has been increased by unity, this will not

FIG. 3
Vapor Pressure of Ammonia Solutions

be sufficient to bring the concentration of the body of the solution back to its original value, for the molecules of solute adsorbed at the surface have displaced molecules of solvent, and enough solute must be added in addition to u to compensate for this addition of solvent in the body of the solution. If one molecule of solute displaces k molecules of solvent, and if the molal ratio solute to solvent is r , then we will have

$$\Gamma = u(1 + kr) \quad (3)$$

Now from the densities of ammonia solutions it will be found that over a range of concentrations greater than we need to consider, that 1 molecule of ammonia replaces 1.33 molecules of water within about 2 per cent. Thus in a 10 molal solution there are 10 moles of ammonia in a liter, and 42.2 moles of water instead of 55.5 as in pure water. So 10 moles of ammonia replace 13.3 moles of water. It seems, therefore, safe to assume that the adsorption of an ammonia molecule at the surface is attended by practically no change

¹ It is convenient to let $x = 0$ be taken as the position of the center of an ammonia molecule when the molecule is "at the surface." It may be remarked that this method of treatment assumes that the molecules are randomly arranged at the surface, and would be rather ambiguous (though it might be used as an approximation) if there were a fixed film of ammonia molecules at the surface. Later calculations will show that there is probably not such a film.

² Though this is apparently not recognized by Lewis and Randall: *loc. cit.*

in total volume, but that on an average 1.33 molecules of water are forced back into the solution. Thus we may take $k = 1.33$. On this basis we have calculated the values of u given in Table II.

TABLE II

Values of $\Delta\gamma$ and the Adsorption in Ammonia Solutions at 18.50°C.

n (Moles per l.)	$\Delta\gamma$ (Dynes per cm.)	Adsorption (Moles per sq. cm.)		
		$\Gamma \times 10^{10}$	$u \times 10^{10}$	$U \times 10^{10}$
1	2.40	.83	.81	1.15
2	4.20	1.27	1.21	1.89
4	6.92	1.70	1.54	2.90
6	9.08	1.775	1.52	3.56
8	10.93	1.79	1.45	4.17
10	12.69	1.86	1.41	4.81
12	14.35	1.93	1.37	5.45
14	16.01	1.99	1.32	6.08

Discussion of the Results

If adsorption takes place in a monomolecular layer, as is the usual assumption, in order to get the actual number of moles per unit surface in this layer we should add to u the number of molecules which would be present in a layer of this thickness if no adsorption took place. Taking the thickness of the layer to be 3.4×10^{-8} from the known partial volume of ammonia, we calculate for the total number of moles per unit surface the values given under U in Table II. For the value of U in molecules per sq. cm. we get for a concentration of 14 M, 3.7×10^{14} , which means that the distance between centers of adjacent ammonia molecules is 5.2×10^{-8} cm., which would seem to indicate that the layer is not filled, as is also indicated by the fact that U does not approach a constant value.

In spite of this fact, one infers, from what is known about molecular forces, and from the numerous researches on similar phenomena, that the adsorbed molecules will be very close to the surface. The average distance of the ammonia molecules from the surface could actually be determined if we had measurements of the dynamic surface tension, γ' , which we knew were measurements of a surface formed so rapidly that no adsorption had taken place, but so slowly that equilibrium was established throughout as far as the solvent was concerned. For, as we have shown¹

$$\lim_{n \rightarrow 0} d\gamma'/dn = -RT \int_0^\infty \log(n_x/n) dx = \int_0^\infty W_x dx \quad (4)$$

where W_x is the work due to the forces of adsorption of bringing a mole of solute from the body of the solution to a point x (so that $RT \log(n_x/n) = -W_x$ for dilute solutions).²

¹ Rice: *loc. cit.*, equation (7). (The sign of the integral in parentheses in this equation is incorrect.)

² See Hersfeld: *Z. physik. Chem.*, 107, 74 (1923).

Now suppose we assume, in order to get an idea of the average distance of the adsorbed molecules from the surface of the solution, that if x is less than some distance a then W_x has a constant value W_a , and for $x > a$ that $W_x = 0$. Then for $x < a$ it is seen that n_x has some constant value n_a , and for

$x > a$ we have $n_x = n$. We then have $\int_0^{\infty} W_x dx = aW_a$, or

$$d\gamma'/dn = aW_a \quad (5)$$

while Gibbs's equation (1) gives us (since for small concentrations $1 + kr = 1$)

$$\begin{aligned} d\gamma/dn &= -RTu/n = -RT(n_a - n)a/n \\ &= -RTa \left(e^{-W_a/RT} - 1 \right) \end{aligned} \quad (6)$$

which gives two equations¹ for a and W_a .

As it seems likely that it will be some time before we can make an unambiguous interpretation of the so-called dynamic measurements of surface tension, we shall attempt to make an estimate of the quantity $\int_0^{\infty} W_x dx$ from the

data at hand. We are able to do this because the curve of Fig. 3 is nearly a straight line over a large range of concentrations. It unfortunately requires, however, that we make an extrapolation from this range of concentrations to infinite dilution which is not entirely without objections.

The molecules at the surface are acted upon by forces of adsorption, and have an energy due to these forces equal, per mole, as we have seen, to W_x . This will always be balanced by the effect due to the increase of concentration, which we may write in general as $u_x \Delta \bar{F} / \Delta n$, where $\Delta \bar{F} / \Delta n$ is a measure of the increase of partial free energy with concentration. We have.

$$u_x \Delta \bar{F} / \Delta n = -W_x \quad (7)$$

Equation (7) may if desired be considered as definitional of W_x , $\Delta \bar{F} / \Delta n$ being the same for changes in concentration at the surface as in the body of the solution. Now in the region in which $\log p$ or \bar{F} has a straight line relation with n , equation (7) becomes

$$u_x \partial \bar{F} / \partial n = -W_x \quad (8)$$

in which case, since $\partial \bar{F} / \partial n$ does not depend on x ,

$$\int_0^{\infty} u_x (\partial \bar{F} / \partial n) dx = u \partial \bar{F} / \partial n = - \int_0^{\infty} W_x dx \quad (9)$$

Since it is seen by Fig. 3 that we always have $\partial \bar{F} / \partial n \geq \Delta \bar{F} / \Delta n$ we have from (1), (3) and (7)

$$-d\gamma/dn / (1 + kr) \geq - \int_0^{\infty} W_x dx \quad (10)$$

Equality occurs where $\log n$ or \bar{F} against n is a straight line.

¹ In these considerations we have tacitly assumed that only one species of ammonia molecule is present, but the considerations remain unaltered if we neglect association at low concentrations (as seems justified by the partial vapor pressure of water) and assume that equilibrium between various hydrates is unaltered at the surface. We neglect ionization of the ammonia, which is permissible since all the measurements used were made at concentrations where it is negligible.

We have plotted $-d\gamma/dn/(1+kr)$ against n in Fig. 4. It is seen that in the region where it is approximately equal to $-\int_0^\infty W_x dx$ the curve is linear and nearly horizontal. Assuming that this relation holds throughout the range of concentrations we have extrapolated the straight part of the curve to $n = 0$, and obtain as the limit 8.8×10^2 erg cm. per mole.

Using this value, and the value of $d\gamma/dn$, which from Fig. 2 is 2.7×10^3 dynes per cm., per mole per cc., we obtain from (4), (5), and (6) the value for a of 1.9×10^{-8} . a is rather sensitive to changes in $\int_0^\infty W_x dx$. Thus if we had

used 10.0×10^2 instead of 8.8×10^2 we would have obtained 2.35×10^{-8} for a . So we cannot fix the value of a with any degree of exactness, but the evidence is in favor of the adsorption taking place close to the surface, i.e. within distances comparable with the size of a molecule, as we should expect. It should be noted that the average distance of the center of an adsorbed molecule from the surface will be $a/2$, or about 10^{-8} cm., according to our estimate.¹

FIG. 4

In order to check our work we have calculated u for several concentrations in Table III. To do this we find $W_a a$ from Fig. 3, calculate W_a , use the curve of Fig. 2 to pick out a concentration, n_a , such that the difference in partial free energy for that concentration and for the concentration, n , of the body of the solution just balances W_a , and finally compute u which is equal to $a(n_a - n)$. The check for the values of u merely indicates that the extrapolation for $\int_0^\infty W_x dx$ or $W_a a$ is a possible one, and does not exclude others. The difference for observed and calculated u 's in the case of $n = 10$ is an indication of how far from being correct our assumption is that $\Delta \bar{F}/\Delta n = \partial \bar{F}/\partial n$, and therefore that we can use the equal sign in (10), for large n 's. It would put us in a position to get a second approximation for $\int_0^\infty W_x dx$, but it is not worth while to do this without better values for the vapor pressures.

It is to be noted that the validity of our estimation of a depends only on the extrapolation for $\int_0^\infty W_x dx$, and on the linearity of the n -log p curve, and not on the actual values of the vapor pressure. From the values of u_x in Table III it will be seen that the linearity must extend about 6 or 7 moles per

TABLE III

Calculation of u from the Extrapolation of Fig. 4 ($a = 1.9 \times 10^{-8}$ cm.)

n (Moles per l)	$\int_0^\infty W_x dx \times 10^{-2}$ (Erg cm. per mole)	$W_a \times 10^{-10}$ (Erg per mole)	u_x (Moles per l)	$u \times 10^{10}$ (Moles per sq. cm.)	$u \times 10^{10}$, obs. (Moles per sq. cm.)
2	8.3	4.36	6.1	1.16	1.21
4	7.9	4.15	8.2	1.56	1.54
6	7.4	3.89	8.6	1.63	1.52
10	6.4	3.37	8.2	1.56	1.41

liter beyond the highest concentration for which we attempt to find $\int_0^\infty W_x dx$.

It may be verified that the particular set of assumptions we make as to the conditions at the surface will not greatly affect our estimation of the average distance of an adsorbed molecule from the surface, which may be defined as $(1/u) \int_0^\infty x u_x dx$. For example, suppose that for $x > a$ we have $W_x = 0$, while W_x is proportional to $a - x$ when x is less than a . Working this case out, and using the same value for $\int_0^\infty W_x dx$ at $n = 0$ as before, (8.8×10^2) we find for a the value 2.6×10^{-8} . In the region where the n -log p curve is a straight line, and approximately elsewhere, we find in this case that the average distance of an adsorbed molecule is $a/3$. It is seen that the agreement with the previous estimate is very close.

Summary

The surface tension of aqueous ammonia solutions has been measured by a modified capillary rise method over a range of concentrations from 0 to 14 moles per liter.

The adsorption, defined in several different ways, of the ammonia at the surface of the solution has been calculated.

From these calculations it appears that there are not enough ammonia molecules at the surface to fill a monomolecular layer, even at the highest concentrations used.

The work, W_x , done on a mole of ammonia when it is brought from the body of the solution to a distance x from the surface is balanced by the change in partial free energy due to that increased concentration of ammonia at the point x . By a consideration of these relations, using the partial pressure curve for ammonia, it is shown that $\int_0^\infty W_x dx$ is a linear, slightly decreasing (in magnitude, disregarding sign) function of the concentration in the body of the solution, for the higher concentrations used. By extrapolating this linear relationship to infinite dilution, and using the laws of dilute solutions, it is estimated that the average adsorbed molecule is about 10^{-8} cm. from the surface. More definite information could be obtained on this point by the measurement of dynamic surface tensions, if they could be unambiguously interpreted.

Berkeley, California.

SOLUBILITY RELATIONS OF ISOMERIC ORGANIC COMPOUNDS

VII. The Mutual Solubility of the Dinitrobenzenes with the Nitroanilines, and of the three Chlorobenzoic Acids*

BY JOHN JOHNSTON AND EDWIN P. JONES¹

In two previous papers it was shown that solutions of the three dinitrobenzenes,² and of the three nitroanilines³ are substantially ideal with respect to the mutual solubility of the several isomers; the present paper extends the measurements to the other nine binary systems—namely of each nitroaniline with each dinitrobenzene—for it was of interest to ascertain if these pairs behave similarly, as in fact they do. The mutual solubility in the three binary systems of the chlorobenzoic acids was also determined; with the results that these systems also prove to be substantially ideal in this respect. On the other hand, the pairs of like isomers of the chloronitrobenzenes and bromonitrobenzenes appear in each of the three cases to form an unbroken series of mix-crystals; *p*-nitrobenzoic acid and *p*-toluic acid show only partial crystal miscibility.

The Dinitrobenzenes with the Nitroanilines

The method of purification and the criterion of purity was the same as previously described.^{2,3} The experimental procedure was somewhat different in that the solid system, contained in a tube surrounded, as before, by a heating coil and a Dewar vessel,⁴ was *slowly* heated, and the temperature at which the last crystal just disappeared was observed directly; during this process the mixture was continuously stirred by the rotation, forward and reverse, of a smaller tube enclosing the thermoelement. This procedure, when carefully carried out, yields a result entirely comparable with that derived from a series of cooling curves, properly interpreted, and is more rapid; it is advantageous particularly for systems in which the stable solid phase crystallizes sluggishly, as proved to be the case with *o*- and *m*-nitroaniline and *m*-dinitrobenzene from some of the mixtures. Each experimental datum in the tables is the average of at least two concordant observations of the last melting temperature *t* (centigrade) of the mixture containing the mol percentage C_A of substance A.

Discussion. In order to secure a better comparative picture of the several solubilities the results were plotted in terms of $\log N$ vs. $1000/T$ on a large scale, and values read off at regular intervals of the reciprocal temperature.

*Contribution from the Department of Chemistry, Yale University.

* Below eutectic temperature.

The data of Tables III and IV show that there is a reasonably close concordance between the several solubility curves for each solid phase in these binary systems. In some cases the concentration for a given temperature is somewhat below, in others it is slightly above, the calculated ideal; and in a few cases the experimental curve appears to cross the ideal. In general, the divergence is greatest when the melting temperatures of the pair of components are farthest apart; but there does not appear to be any specific difference as between systems composed of a pair of dinitrobenzenes or of nitroanilines, on the one hand, and of a dinitrobenzene and a nitroaniline, on the other. It is doubtful in how far this last statement can be generalized; for there will almost certainly prove to be cases in which the solubility of an isomer A, in mixture with isomer B having another pair of substituent groups, is not ideal even though the solubility both of A and B is substantially ideal in binary mixtures of the triads of A and of B respectively.

Another illustrative comparison is between the eutectic temperature as observed, and that derived by extrapolation to intersection of the pair of experimental solubility curves, as listed in Table V. The extrapolated temperature is, on the average, 0.8° higher than the observed which, being independent of the relative amounts of liquid and solid, is more likely to be

TABLE V

The Observed Eutectic Temperature, and the Extrapolated Eutectic Temperature and Composition (in mol percentage to the nearest 0.1%) in the Several Binary Systems of the Dinitrobenzenes (D) and the Nitroanilines (N).

right. This indicates that the method of experiment—namely to observe the temperature at which the last crystal disappears when the system is slowly heated—tends to yield somewhat too high temperatures for a given gross composition; and this would be expected since the real concentration of the disappearing solid phase in the liquid is somewhat smaller than the gross concentration in the mixture as a whole. This is just the converse of what happens in the more usual method of observing the cooling or freezing curve,

where it is necessary to allow for the amount of solid which has separated out at the moment when the temperature is read; otherwise, the temperature read as corresponding to a given initial composition is too low.⁷

The Chlorobenzoic Acids

To purify each of these substances, it was dissolved in a solution of sodium hydroxide, which was then filtered and acidified; it was recrystallized from water, and then sublimed. The product in each case showed an acceptable cooling curve. The observations on the three binary systems, together with a few made in the ternary mixtures, are listed in Table VI.

⁷ Cf. paper II of this series, in which this correction is discussed in detail.

The ideal values, computed on this basis, together with those interpolated on a large scale curve at a series of values of $1000/T$, are given in Table VII. It also contains results interpolated from Holleman's data on the three systems with benzoic acid as second component; these show that the behavior in these three cases is very little different from the three pairs of chlorobenzoic acids, differing little from the ideal.⁸ Indeed the agreement is in all probability considerably better for the systems with benzoic acid than is indicated by the figures in Table VII; for, to be strictly comparable with ours, they should be raised by 1-1.5%. The basis for this statement is that Holleman's results on the pairs of chlorobenzoic acids (which he also investigated) are lower by 1-1.5% (and, it may be added, somewhat less regular) than ours; the higher temperatures recorded by him for a given mixture are largely due, presumably, to a difference in method of experiment.

TABLE VII
Solubility of the Chlorobenzoic Acids, in terms of C_A (mol percentage of solute) at even intervals of $1000/T$

(a) A = <i>ortho</i>							
	1000/T	2.45	2.50	2.55	2.60	2.65	
Solvent	t	135.1	126.9	119.1	111.5	104.3	
Ideal		91.6	78.7	68.0	58.8	51.0	
<i>m</i>		90.9	77.7	66.6	57.1		
<i>p</i>		90.4					
benzoic acid ⁹		89.0	75.3	64.0	54.9	47.3	
(b) A = <i>meta</i>							
	1000/T	2.35	2.40	2.45	2.50	2.55	2.60
	t	152.5	143.6	135.1	126.9	119.1	111.5
Ideal		97.7	85.4	74.4	64.7	56.6	49.5
<i>o</i>		97.9	83.2	71.8	62.4	54.7	47.9
<i>p</i>		97.5	83.0				
benzoic acid ⁹		95.5	81.0	68.8	58.4	49.6	42.1
(c) A = <i>para</i>							
	1000/T	2.00	2.10	2.20	2.30	2.40	
	t	226.9	203.1	181.4	161.7	143.6	
Ideal		82.9	58.2	42.3	31.8	24.7	
<i>o</i>		81.0	54.8	37.3	26.3	19.0	
<i>m</i>		81.4	56.5	40.8	29.8	22.0	
benzoic acid ⁹		83.8	57.6	39.5	27.2	18.7	

⁸ The divergence in the case of *para* between ideal and experimental is probably due to an error in its heat of melting, this in turn being due to some decomposition at its melting temperature, which is relatively high (239.5°).

⁹ Interpolated from the data of Holleman, (Rec. Trav. chim. 31, 244 (1912)), on the basis of the melting temperature as given by him. This is not a strictly logical mode of comparison, but is however the least arbitrary.

Comparison of the observed eutectic temperature with that extrapolated from the solubility curves shows that here again the latter is slightly higher.

Components		Eutectic Temperature		Eutectic Composition	
1	2	Observed	Extrapolated	C ₁	C ₂
<i>o</i>	<i>m</i>	108.7	109.0	54.2	45.8
<i>o</i>	<i>p</i>	131.8	131.8	84.7	15.2
<i>m</i>	<i>p</i>	140.0	140.5	79.2	20.8

In the ternary mixtures the temperatures observed lie close to those calculated for the same percentage, in binary mixture, of the substance which is the stable solid phase. The composition of the ternary eutectic is about 48.3% *ortho*, 44.0% *meta*, 7.7% *para*.

Some Cases of Crystal Miscibility

In an earlier paper it was remarked that solid solution apparently does not occur to any appreciable extent as between the three position isomers C_6H_4XY . This statement, the validity of which is extended by the data just presented, implies that the crystallographic units of these three substances are unlike; as indeed one would expect, except possibly when X is a group large enough to dwarf the importance of the ring. Presumably therefore the occurrence of mix-crystals as between the pairs of components C_6H_4XY and C_6H_4XZ is limited to the cases in which the relative position of the substituents is the same; in other words, we shall not with this type of compound find mix-crystals except we are dealing with a pair of *ortho*, or of *meta*, or of *para* compounds. Even in this case it is to be expected that solid solution would be complete only when the groups Y and Z are very similar (e.g. both halogens) but would extend over a narrower and narrower range with increasing disparity of Y and Z. Indeed our data on the like pairs in the dinitrobenzene-nitroaniline systems show that the groups NO_2 and NH_2 are in this respect so unlike that there is no appreciable mutual solid solubility. The scarcity of relevant experimental data led us to make a few observations, more or less preliminary in character, which indicate that there is complete crystal miscibility between like pairs of the chloronitrobenzenes-bromonitrobenzenes, but incomplete miscibility between *p*-nitrobenzoic acid and *p*-toluic acid.

The primary freezing temperature (t_L) was observed visually as that at which the last crystal disappeared when the temperature of the system was raised very slowly; equilibrium throughout the sample (the weight of which was from 0.2-0.4 gram) was assured by the reciprocating acting of a mechanical stirrer which included the thermoelement, a single junction of #36 constantan and of #40 copper. These observations are, it is believed, accurate to $\pm 0.2^\circ$. The secondary freezing temperature was derived from observation of the break on a controlled heating curve; in this case, owing to poor heat conduction through the solid mass, the accuracy is less good—of the order $\pm 0.3-0.5^\circ$.

The Chloronitrobenzene-Bromonitrobenzene Pairs

The *meta* pairs had previously been investigated by Küster¹⁰ and later by Hasselblatt,¹¹ with concordant results; we worked therefore only with the *ortho* and *para* pairs. Subsequent to the completion of the work it was found that one of the substances in each pair had not been purified sufficiently to make the numerical results of absolute significance; consequently they are not reproduced here. They indicate very clearly however that there was complete miscibility (of type I) as between the samples investigated, in harmony with the previous results on the *meta*-pair. It will be interesting to ascertain if in all cases of this type, when one pair forms a complete series of solid solutions, the other two pairs behave similarly. More accurate data on the liquidus and solidus curves, and on the heat of melting of the components, would enable one to make another test of the validity of the van Laar ideal equation¹² for the case of complete solid solution.

The Pair *p*-Toluic Acid-*p*-Nitrobenzoic Acid

The results, presented in Table VIII, show that in this case there is only partial miscibility on either side at the temperature in question. This indicates that in this respect the group CH₃ resembles NO₂ more closely than does NH₂, but that the resemblance is less than that between Cl and Br.

Summary

Investigation of each of the 30 solubility curves in the 15 possible binary mixtures of the dinitrobenzenes and nitroanilines shows that the curve is in all cases not far from the ideal calculated from the heat of melting; these divergences, though small and in either direction, are real, but bear no obvious relation to any other measured properties of the pair of compounds. There is no appreciable formation of mix-crystals even between those three pairs in which the relative position of the substituents is the same. On the other hand, the three like pairs of the chloronitrobenzenes and bromonitrobenzenes form a complete series of solid solutions; *p*-toluic acid and *p*-chlorobenzoic acid however show only partial mutual crystal miscibility.

THE VISCOSITY OF SUPERSATURATED SOLUTIONS. I

BY I. K. TAIMNI

It is well known that solutions of most substances can be cooled below their saturation point without crystallization, provided due precautions are taken to prevent the inoculation of the solution with the minutest crystal of the solid present in the solution. But if the process of cooling is continued, a temperature is reached at which the solid phase makes its appearance even though the solution has been protected from introduction of germ crystals from outside. This phenomenon is known as the spontaneous crystallization of supersaturated solutions.

H. A. Miers and Florence Isaac¹ examined supersaturated solutions of some salts like sodium nitrate and sodium chlorate and showed that, corresponding to every concentration of the salt, there was a definite temperature, at which spontaneous crystallization took place. The line joining the temperatures at which solutions of different concentrations crystallized out spontaneously was found to be approximately parallel to the solubility curve of the salt and was called the "supersolubility curve." An examination of the refractive index of the solutions showed that, as each solution was progressively cooled, its refractive index continued to increase, but, at a certain temperature below the solubility temperature, its value reached a maximum and then began to fall. If the solutions were allowed to cool at rest in presence of growing crystals, this fall was gradual; but if it was stirred during the process of cooling, the fall in the value of the refractive index was abrupt and was followed by a shower of crystals. When the values of the temperatures at which the maximum refractive index was attained were plotted against the concentrations of the solutions, a curve identical with the "supersolubility curve" was obtained. The sudden fall in the value of the refractive index was attributed by Miers to the sudden weakening of the solution as a result of the spontaneous formation of a large number of crystal nuclei in the solution which rapidly grow in size and produce the shower of crystals referred to above.

It, therefore, follows from the work of Miers that a definite change takes place at the temperature of spontaneous crystallization, a temperature at which the solution passes from the "metastable" into the "labile" state.

A number of investigators have examined various physical properties of supersaturated solutions with a view to find out whether the solutions undergo some sudden change at the solubility temperature, a change which will manifest itself by the curve—representing the physical property in question—showing a break at the saturation point. Thus C. Heim² examined the electric conductivity and showed that none of the salt solutions examined exhibited

¹ J. Chem. Soc., 891, 413 (1906).

² Ann. Physik Chem., (3) 27, 673 (1886).

any sudden change in their specific resistance as they passed into the supersaturated condition. W. W. J. Nicol¹ examined the specific viscosity of solutions of some salts a few degrees below the solubility temperature, and found that the viscosity curves are perfectly regular at the saturation point, there is nothing to indicate any change in the constitution of the solutions as they pass from the unsaturated into the supersaturated condition. A similar result was obtained by K. Bindel² who examined the specific gravities, specific heats, and heats of solution of supersaturated salt solutions. From the above investigations it is evident that a solution which is progressively cooled undergoes no sudden change in passing through the solubility temperature.

Miers was the first to demonstrate the existence of a second definite critical point in the condition of a cooling solution. The first critical point is, of course, the solubility temperature at which the solution passes from the unsaturated into the "metastable" region, a region in which the introduction of a crystal from outside is necessary to start the process of crystallization. The second critical point is the "supersolubility" temperature at which the solution passes from the "metastable" into the "labile" region, a region in which crystals begin to form and grow spontaneously in the supersaturated solution.

While the curves representing various physical properties remain perfectly regular in passing through the solubility temperature, Miers found that the refractive index curves of solutions passed through maxima at their respective supersolubility temperatures. It was, therefore, expected that an examination of other physical properties of supersaturated solutions might reveal similar irregularities in the curves representing those properties. A physical property suitable for an investigation of this kind is viscosity. The present investigation was undertaken with a view to measure the viscosity of supersaturated solutions. It will be seen that the viscosity curves, as far as they have been traced, remain quite regular. We are, therefore, justified in concluding that the viscosity of a solution undergoes no sudden change below the saturation temperature.

The viscosity measurements were made by means of an apparatus devised by Scarpa³ and used by F. D. Farrow⁴ for measuring the viscosity of soap solutions. It was necessary to introduce certain modifications in this apparatus to prevent the inoculation of the supersaturated solutions with germ crystals carried by dust particles or formed at the margin of the solution through evaporation of the solvent.

The method consists in measuring the time t_1 , taken in drawing up, by suction, a fixed volume of the solution through a capillary tube, and the time t_2 which this volume of the solution takes in flowing out through the capillary tube under the action of gravity.

¹ J. Chem. Soc., 51, 389 (1887).

² Ann. Physik Chem., (3) 40, 370 (1890).

³ Gazz., 40, 271 (1920).

⁴ J. Chem. Soc., 101, 347 (1912).

Given constant conditions, the viscosity of any liquid, according to Scarpa, is proportional to the expression $\frac{t_1 \cdot t_2}{t_1 + t_2}$ (t_2 measured in seconds).

$$\text{or} \quad \eta_{\text{liquid}} = K \times \left(\frac{t_1 \cdot t_2}{t_1 + t_2} \right)_{\text{liquid}}$$

where K is a constant which can be determined by calibrating the apparatus with water.

The great advantage of this method over the ordinary method lies in the fact that it is not necessary to measure the density of the liquid. It is extremely difficult to avoid the inoculation of a supersaturated solution with germ crystals in the process of the density determination, and hence the ordinary method which requires a knowledge of the density of the solution at each temperature is practically inapplicable in the case of supersaturated solutions.

The work of numerous investigators has shown that the crystallization of a supersaturated solution is brought out by germ crystals introduced from outside. Provided the vessel containing the solution has been properly cleaned and the substance has been completely dissolved, the inoculation of the solution with germ crystals can take place either through the dust particles suspended in the atmosphere, or through evaporation of the solvent and the consequent deposition of minute crystals at the margin of the solution. Modifications were, therefore, introduced into Scarpa's apparatus to guard against the inoculation of the solutions in either of these ways, and it was thus found possible to cool the solutions far below their respective solubility temperatures. Of course, in some cases, crystallization took place, owing to the formation of a few nuclei in the solution itself, but even in such cases, the crystallization was so slow that it was possible to determine the viscosity of the solution at temperatures some degrees below the temperature of spontaneous crystallization.

The viscometer and the accessory apparatus used are shown in Fig. 1. A is a cylindrical glass vessel with a side tube F. The mouth of the vessel is fitted with a rubber stopper through which passes a glass tube G connected at its lower end with a viscometer consisting of a bulb B to which a capillary tube C is attached. The glass tube G can be put into communication with the aspirator H and thus suction applied to fill the bulb of the viscometer with the solution contained in the vessel A. The suction exerted depends on the difference of water level in the aspirator H and the beaker placed underneath, and its value is measured by means of the water manometer M. Before connecting the aspirator H with the viscometer, the pressure is always brought to a constant value—30 cm—by adding to or withdrawing water from the beaker. The difference in the manometer reading before and after each reading of time is not greater than *one* millimeter and thus the pressure remains practically constant during the process of filling the viscometer bulb.

The U-tubes D and E are connected with the two-way tap T which puts one or the other of the U-tubes into communication with the air continued in

the aspirator S. The mouth of this aspirator is fitted with a rose for producing a fine spray of water. This spray removes all the dust particles from the air contained in the aspirator, and thus all the air coming into contact with the surface of the supersaturated solution is free from crystal germs, which if present will bring about the release of supersaturation even in the "meta-stable" region. It is not possible to purify the air by passing it through water as this would disturb the pressure.

FIG. 1
Apparatus for measuring Viscosity of Supersaturated Solutions

When the solution is to be sucked up into the bulb of the viscometer, the tap T is turned so as to put the U-tube D into communication with the air in the aspirator S, the clip at P is closed, and suction applied by opening the clip at K. When the bulb is to be emptied the clip at K is closed, and both the U-tubes are simultaneously put into communication with the air in the aspirator S, by turning the tap T and opening the clip at P.

Both the U-tubes contain a small quantity of water which serves to maintain a vapour pressure at the surface of the solution higher than the vapour-pressure of the solution itself. This prevents any evaporation of the solvent from the surface of the solution and the consequent formation of minute crystals near the margin of the solution. Theoretically, water should distil from the U-tubes, into the solution and decrease its concentration but in practice the quantity of water so carried over is so small as to be negligible.

The aspirator L and the wash-bottle N serve to pass a current of dust-free air through the whole apparatus when necessary. This sweeps away any dust particles that may be hanging in the air enclosed within the apparatus. After closing the clip at Q, water is made to flow into the aspirator L from the tap J. The air in the upper part of the aspirator is forced out, and after being washed in the Wolff's bottle N, is made to circulate through the whole apparatus and then ejected into the aspirator S. When the aspirator L becomes full with

water, the clip at Q is opened and water made to flow out through the opening near the bottom of the aspirator. Purified air from the aspirator S fills the aspirator L and can be circulated through the aspirator as before.

The parts of the apparatus surrounded by a dotted line are enclosed in a gas-heated water thermostat with glass sides. For temperatures below the room temperature iced water was added from time to time as required.

As solutions of widely different viscosity were investigated, it was necessary to use viscometers with capillary tubes of different radii. With a particular solution, that viscometer was used which made the time of flow convenient to measure. Three viscometers were used but as these were calibrated with water, it was not considered necessary to measure their essential dimensions.

For convenience sake, values of the expression $\left(\frac{t_1 \cdot t_2}{t_1 + t_2} \right)$ are plotted against temperature. The absolute viscosity is proportional to this expression and can be obtained by multiplying the expression by the "viscosity factor" given with each curve. The value of this "viscosity factor" was obtained by alibrating the particular viscometer used with water. As the value of the expression $\left(\frac{t_1 \cdot t_2}{t_1 + t_2} \right)$ varies to a slight extent with the height of the liquid in the vessel A, the "viscosity factor" gives only approximately the absolute viscosity. The relative value of the viscosity for each solution is, however, correctly given by the expression $\left(\frac{t_1 \cdot t_2}{t_1 + t_2} \right)$ because the height of the solution remains constant throughout one series of experiments.

In carrying out an experiment, a solution of known concentration was prepared by introducing a weighed quantity of the substance into a small flask and adding a measured quantity of water. The mouth of the flask was closed with a rubber stopper which was made quite secure in its place by means of a piece of string. The flask was heated in boiling water till all the solid had gone into solution. The rubber stopper was then removed from the flask and the solution—still much above its solubility temperature was carefully transferred to the bottom of the vessel A with the help of a piece of glass tubing. The rubber stopper carrying the viscometer was carefully replaced, the whole apparatus was lowered well beneath the surface of water in the thermostat, and after adjusting the viscometer in a vertical position, the solution was allowed to attain the constant temperature of the thermostat. The times taken in the ascent and descent of the solution were measured by means of a stop watch, several readings being taken for each temperature.

The times of ascent and descent of the solution are influenced by the temperature and the pressure, and experiments were therefore made to determine roughly the extent to which a slight error in the measurement of these affected the time of ascent or descent. It was found that a difference of pressure of 1 cm altered the time of ascent by about one per cent. The error in the measurement of pressure which could at most be .5 mm, could not, therefore affect

the time of descent by more than .05%. The effect of slight error in the measurement of temperature depended to a very great extent on the nature of the solution whose viscosity was being measured, but even in the case of those solutions whose viscosity was greatly affected by change of temperature, an alteration of .05°C did not affect the time of ascent or descent by more than .5%.

FIG 2.

Viscosity of Sodium Nitrate Solutions

I. Solution contains 50% Salt

II. Solution contains 51% Salt

Viscosity Factor 33×10^{-5}

Solutions of six substances—sodium nitrate, sodium chlorate, copper sulphate, sodium thiosulphate, tartaric acid and cane sugar—were examined. Two solutions of different concentrations were investigated in the case of each substance, in order to obtain an approximate idea of the effect of change of concentration on the viscosity of the solution.

Sodium Nitrate, Sodium Chlorate and Copper Sulphate

The curves in Figs. 2 and 3, which are very much alike, show the change of viscosity with falling temperature for solutions of sodium nitrate and sodium chlorate. It will be seen that the curves remain quite regular in pass-

ing through the temperature of spontaneous crystallization as determined by Miers. It was not possible to measure the viscosity at temperatures very much below the temperature of spontaneous crystallization, because, when the solutions were cooled a few degrees below this temperature, minute crystals began to appear in the solution and ultimately blocked the capillary tube. In no case did the crystals make their appearance in the "metastable" region, but only after the solution had been cooled a few degrees below the tempera-

FIG. 3
Viscosity of Sodium Chlorate Solutions
I. Solution contains 53.4% Salt
II. Solution contains 54.4% Salt
Viscosity Factor 33×10^{-5}

ture of spontaneous crystallization. It follows, therefore, that the appearance of crystals was due to spontaneous formation of crystal nuclei in the solution itself and not to the introduction of germ crystals from outside.

The curves in Fig. 4 for copper sulphate solutions are similar to those obtained for sodium nitrate and sodium chlorate, except that the solutions could be cooled much below the solubility temperature before crystals began to appear in the solution. While in the case of sodium nitrate and sodium chlorate solutions spontaneous crystallization took place roughly about 10 degrees below the saturation temperature, in the case of copper sulphate solutions, the first crystal did not form until the temperature of the solution had been reduced 30°–40° below the saturation point. No definite supersolubility data were available, but the curves, as far as they could be traced remained perfectly regular.

Sodium Thiosulphate, Tartaric Acid and Cane Sugar

The curves for these substances are given in Figs. 5-7 and differ in some ways from the preceding curves. Not only is the initial viscosity very much greater than in the case of the preceding three substances, but it also increases very rapidly as the temperature is lowered. For example, the viscosity of 66% tartaric acid solution at 10° is almost double that at 20° and the viscosity of 75% cane sugar solution at 16° is almost three times that at 26°.

FIG. 4

Viscosity of Copper Sulphate Solutions

I. Solution contains 38.3% hydrated Salt

II. Solution contains 35.1% hydrated Salt

Viscosity Factor 33×10^{-6}

Another peculiarity in the case of these substances is the divergence of the two curves representing two different concentrations of the same substance. This means that the difference in viscosity of the two solutions becomes greater and greater as the temperature is lowered. In the case of sodium thiosulphate solutions, the difference at 60° is about 5 units and at 5° about 35 units. In the case of tartaric acid solutions, the difference at 60° is about 10 units and

at 10° about 200 units. In the case of cane sugar, the difference at 60° is about 20 units and at 15° it reaches the remarkable value of about 1350 units.

Although solutions of these substances were cooled 30° – 45° below their respective solubility temperatures, no sign of spontaneous crystallization was

FIG. 5
Viscosity of Sodium Thiosulphate Solutions
I. Solution contains 75% hydrated Salt
II. Solution contains 70% hydrated Salt
Viscosity Factor 24×10^{-4}

obtained. In some cases, after finishing the viscosity measurements, the solutions were placed in a freezing mixture of ice and salt, but even then no crystallization took place.

The present investigation was primarily undertaken with the object of finding out whether the viscosity curves of cooling solutions suffer any marked change in passing through their respective supersolubility temperatures. Supersolubility data were available only in the case of two substances, sodium nitrate and sodium chlorate. Viscosity curves for solutions of these substances show no break in passing through the supersolubility temperatures as

determined by Miers. In the case of the other four substances, supersolubility data were not available, but the viscosity curves remain quite regular even 30° – 45° below the saturation temperatures.

Of these four substances, solutions of only one, namely copper sulphate, exhibited anything like the phenomenon of spontaneous crystallization

FIG. 6

Viscosity of Tartaric Acid
 I. Solution contains 61.2% Acid
 II. Solution contains 66.6% Acid
 Viscosity Factor 24×10^{-4}

minute crystals making their appearance in the highly supersaturated solution at sufficiently low temperatures. In the case of sodium thiosulphate, tartaric acid and cane sugar solutions, there was no sign of spontaneous crystallization. Either the solutions of these substances do not show the phenomenon of spontaneous crystallization at all, or the lowest temperatures reached were still above their supersolubility temperatures. This inability on the part of these highly supersaturated solutions to crystallize out spontaneously may be attributed to the high viscosity of the liquid, on account of which the nuclei

formed in the solution take a very long time to attain the size at which they become visible. This latter explanation does not, however, seem to be tenable, at least in the case of sodium thiosulphate solutions, which in spite of being very viscous at low temperatures, crystallized out immediately on inoculating the solutions with a minute crystal of the salt.

FIG. 7
Viscosity of Cane Sugar Solutions
I. Solution contains 75% Sugar
II. Solution contains 70% Sugar
Viscosity Factor 22×10^{-3}

Summary

(1) Viscosities of supersaturated solutions of six substances—sodium nitrate, sodium chlorate, copper sulphate, sodium thiosulphate, tartaric acid, and cane sugar—have been determined by means of an apparatus devised by Scarpa, and modified by the author in a suitable manner for measuring the viscosity of a supersaturated solution.

(2) It has been shown that the viscosity curves, in the case of sodium nitrate and sodium chlorate solutions remain quite regular not only in passing through the saturation temperature but also in passing through the temperatures of spontaneous crystallization as determined by Miers.

The refractive index curves of these solutions, according to Miers, pass through maxima at the temperatures of spontaneous crystallization. In the

case of the other four substances examined, no 'supersolubility' data are available but the viscosity curves, as far as they could be traced, (30° – 45° below the saturation temperature) remained perfectly regular.

(3) Out of the four substances, only one, viz: copper sulphate, exhibited the phenomenon of spontaneous crystallization at sufficiently low temperatures. In the case of sodium thiosulphate, tartaric acid and cane sugar solutions there was no sign of spontaneous crystallization even when the temperature was lowered 30° – 45° below the saturation temperature.

I desire to express my thanks to Professor Donnan for his helpful criticism and valuable advice during the course of this investigation.

AN EXAMINATION OF PATRICK'S THEORY OF ADSORPTION

BY SIDNEY J. GREGG

Much interesting material has been put forward recently by Patrick and his co-workers, which is regarded as supporting the capillarity theory of adsorption proposed in 1920 by Patrick and McGavack.¹ The present author's investigation² of the adsorption of gases by charcoal led him to examine along with other theories of adsorption, that of Patrick and McGavack, and the result of this examination is detailed below.

Patrick assumes that adsorption is due to condensation of the vapour to the liquid state in the capillaries of the adsorbent, the necessary reduction in vapour pressure occurring in consequence of the sharp concavity of the liquid meniscus. The true measure of pressure will therefore be the "relative pressure" p/p_0 , where p is the equilibrium pressure of the adsorbed vapour, and p_0 its saturated vapour pressure at the temperature of experiment; the amount of substance adsorbed should be expressed, not in weight, as is customary, but in terms of its liquid volume, which must however be corrected for the fact that it is expanded owing to the negative hydrostatic pressure exerted by the meniscus. This correction Patrick empirically assumes to be given by introducing the surface tension of the liquid as a correction-factor, since in some cases the relationship $\beta\sigma^{1/3} = \text{a constant}$, is known to hold between the surface tension σ and the compressibility β of liquids. Since the corrected volume adsorbed at a given relative pressure p/p_0 , should be independent of the nature of the adsorbed substance and of temperature, Patrick arrives at the formula

$$V = K \left(\frac{p\sigma}{p_0} \right)^{1/N}$$

where V is the amount of substance adsorbed expressed as volume of liquid, per gram of adsorbent, and K and $1/N$ are constants for a given adsorbent, no matter what the temperature or the substance adsorbed.

Hence on plotting $\log V$ against $\log p\sigma/p_0$, all points for a given adsorbent should fall on the same straight line, independent of temperature and nature of adsorbed substance.

The first case examined by Patrick,³ viz. the adsorption of sulphur dioxide by silica gel at temperatures from -80° to 100° , fulfills this condition fairly well, though the present author has found that the best line through the points is not quite straight.

But the question arises, is surface tension the only quantity which will cause coincidence of the otherwise widely separated $\log V$ - $\log p/p_0$ curves for

¹ Patrick and McGavack: J. Am. Chem. Soc., **42**, 946 (1920).

² J. Chem. Soc., 1927, 1494.

³ Patrick and McGavack: loc. cit.

different temperatures? Since adsorption falls off with rise of temperature, any quantity which also decreases with rising temperature, will, like σ , bring the curves closer together. If, for instance, the simple quantity $1/T$ be employed (where T is absolute temperature) and $\log p/p_0 T$ be thus plotted against $\log V$ for the above experiment, the curves for the different temperature are brought closer together, though the degree of coincidence is not so good as Patrick's.

FIG. 1

Plot of $\log V$ against $\log \frac{p}{p_0 T}$ and $\log V$
against $\log \frac{p\sigma}{p_0}$ for C_2H_5OH , CCl_4 and H_2O .

On applying the same treatment to the data for butane¹ at 0° , 20° and 30° , it is found that equally good results are obtained with either σ or $1/T$; similarly with ammonia, an equally good degree of coincidence is obtained with either quantity, though in both cases the best line through the points is not quite straight, showing that they do not fit accurately an equation of the Patrick type.

When Patrick's formula is applied to his measurements² for ethyl alcohol, carbon tetrachloride and water vapour on silica gel, one curve (that for water) still remains widely divergent from the others; whereas on plotting $\log p/p_0 T$ instead of $\log p\sigma/p_0$, a considerably greater degree of coincidence is obtained (Fig. 1). This throws much doubt on the validity of Patrick's formula, in spite of his special explanation for the position of the water curve; he points out that in this experiment the water was slow in attaining equilibrium, and moreover exhibited hysteresis (i.e. the sorption and desorption curves did not coincide) which indicates that the equilibrium was not a true one. This he explains by the fact that the viscosity of water below 30° , unlike that of most other substances, increases with fall of pressure, so that owing to the large

¹ Patrick and Long: J. Phys. Chem., 29, 336 (1925).

² Patrick and Opdycke: J. Phys. Chem., 29, 601 (1925).

negative hydrostatic pressure exerted by the meniscus, the viscosity is increased. This increases the time required for the attainment of equilibrium so that the time occupied by the water measurements was not long enough for true equilibrium to be reached.

That this explanation is unlikely is shown by the following considerations: the magnitude of the negative pressure on the liquid at 30° when $p = 0.1$ mm., say, (calculating according to the Gibbs' formula quoted by Patrick¹) is 130

FIG. 2

Plot of $\log V$ against $\log \frac{p}{p_0}$ and $\log V$ against $\log \frac{p}{p_0} \cdot \frac{1}{T}$ for CO_2 and N_2O .

atmospheres, which would give rise to a viscosity change of less than 0.3% (Cohen: "Piezochemie," p. 259). It is difficult to believe that this small change in viscosity could have such a large effect on the rate of movement of water, for this movement would no doubt be analogous to flow through a capillary tube, the velocity of which decreases in a linear manner with increasing viscosity.

A further case indicating the inadequacy of the Patrick formula, is the adsorption of nitrous oxide and carbon dioxide² by silica at 0° , 20° and 30° , where the plot of $\log V$ against $\log p/p_0$ gives widely separated curves. (Fig. 2). Again Patrick uses a special explanation, pointing out that according to Freundlich³ the surface tension of a liquid in a concave surface is smaller than in a plane one, this effect becoming appreciable when the radius of curvature is less than 10^{-6} cm.; then by an application of the well-known Kelvin formula for the relationship between the radius of a capillary r , and the vapour pressure over a liquid in the capillary, viz.

$$\log p/p_0 = -2d\sigma/Dp_0r$$

¹ Patrick and McGavack: loc. cit., 975.

² Patrick, Preston and Owens: J. Phys. Chem., 29, 421 (1925).

³ Freundlich: "Kapillarchemie," 63 (1923).

where D and d are the liquid and vapour densities respectively, he obtains the corrected value for the surface tension. This proceeding must be regarded as questionable, however, for the values of r dealt with are of the order 5×10^{-8} cm., i.e. approximately the diameter of a single molecule; and an extrapolation down to molecular dimensions of a formula which is essentially statistical in nature and applies only to a substance in bulk, seems, as indeed Patrick admits elsewhere,¹ scarcely permissible. The unsatisfactory nature of the method, is emphasized by the fact that even after thus correcting, one curve still remains widely divergent. On substituting $1/T$ for σ on the contrary, all the curves come very close together, no further modifications of the formula being necessary. (Fig. 2).

In view of the above examination, there seems little doubt that the Patrick formula is unsatisfactory; the presence in it of the surface tension σ is shown to be unjustified, even the entirely empirical quantity $1/T$ securing for the formula a closer agreement with experimental data. Even when so amended, however, the formula can be regarded only as a purely empirical relationship, which does not provide a basis for a theory of adsorption.

The rejection of Patrick's formula in the form suggested by him does not of course rule out the possibility of capillary condensation, but it shows that the present evidence for Patrick's view is incomplete.

MOLECULAR ORIENTATION AT SURFACES OF SOLIDS. II. THE WORK OF ADHESION OF THE SATURATED FATTY ACIDS FOR WATER*

BY A. H. NIETZ

The method used in calculating the work of adhesion and the measurements upon which it is based have been discussed in the previous paper. In fact the measurements, repeated in Table I, were there recorded without comment and are made the subject of a separate communication here, since they seem to open up new questions.

FIG. 1.

TABLE I

Acids	θ	T_R	W	Acids	θ	T_R	W
Caproic	45	30	87.0	Tridecylic β	95	40	36.5
Caprylic	60	38	66.2	Myristic	115	25	32.0

* Communication No. 323 from the Research Laboratory of the Eastman Kodak Company. Read at the Richmond meeting of American Chemical Society.

These measurements are graphically summarized in Fig. 1, in which work of adhesion is expressed as the ordinate and n as the total number of carbon atoms on the horizontal axis. The points in all cases represent averages where more than one determination was made.

It is seen at once that the well-known alternation between the acids of odd and even carbon atoms is very pronounced. The magnitude of the alternation is greater for work of adhesion than it is perhaps for any other physical property. The two enantiotropic forms of the odd acids have been

FIG. 2

measured and the results are shown in the figure. The lower curve is for the even acids and the β odd acids fall approximately on this curve, and the upper curve is for the α odd acids. The α odd acids are stable only at temperatures relatively near their melting points. The β odd acids of the higher members are the forms stable at ordinary temperatures. The lower members of the β odd acids are stable only at relatively low temperatures. In order to measure the β form of pelargonic acid (9 carbon atoms) for example, it was necessary to freeze the acid with carbon dioxide snow and to make the measurements very quickly in water as near the freezing point as possible.

In Fig. 2 the detailed values for the contact angle of the acids are shown. It is seen that the extent of alternation exhibited by the odd and even acids is very great. In Fig. 3 the percentage reduction of the surface tension of water is plotted against the number of carbon atoms. Here, also, a certain amount of alternation is evident. It is therefore natural to expect that the values of work of adhesion ($W = T(1 + \cos \theta)$) should show a considerable degree of alternation. In Figs. 4-9 there are summarized most of the existing

FIG. 3

FIG. 4

FIG. 5

FIG. 6

Fig. 7

Fig. 8

data on other physical properties of the saturated fatty acids. Most of these show the alternating effect quite clearly. Fig. 9 is of particular interest. It is taken from a recent paper by Smith and Boone on "The Alternating Behavior of Fatty Acids added to Rubber Compounds."¹ The curve shown for

FIG. 9

FIG. 10.

the tensile strength of rubber against the number of carbon atoms of the acids added (1/15 mol. per 100 gms. of rubber) represents the only data so far discovered which seem to bear any relation to the results of the present work on adhesion of the fatty acids. In Fig. 9 the odd acids have a maximum at about 7 carbon atoms and the even acids at about 14. The general average maximum is in the neighborhood of 11 carbon atoms. The phenomena ex-

¹ Ind. Eng. Chem., 19, 398 (1927).

hibited in Fig. 9 are undoubtedly related in some way to work of adhesion shown in Fig. 1. It should eventually be possible to correlate these properties.

The explanation adopted for the alternation exhibited by the odd and even acids is that first suggested by Garner and Randall in a recent paper on the "Heats of Crystallization."¹ They attribute the difference between an even acid and the next higher odd acid to a change in the crystal structure. The x-ray crystal structure suggested for these various acids is shown in diagram in Fig 10, in which I is the structure of the even acids, II that of the α

FIG. 11

odd acids, and III the β odd acids. The type of structure represented by I has been thoroughly studied and verified by the work of Bragg and Müller and Shearer and others, also agreeing with results of Langmuir on the dimensions of the molecule. The crystallized acids consist of parallel chains of carbon atoms, the unit cell consisting of two molecules placed end to end with their carboxyl groups adjoining. The angle between two adjacent carbon atoms has been definitely shown to be about 109° or the same as the angle between carbon atoms in the diamond. This permits of the pattern indicated either by the full line or the dotted line. In I and III Garner and Randall assume that the carboxyl groups face each other as shown, in each case a hydroxyl group facing an oxygen. In case II the hydroxyl and oxygen groups are staggered, one oxygen on one side, and one hydroxyl on the other being left relatively free. Consequently, we should expect that in cases I and III the residual valences of the oxygen and hydroxyl groups would be rather completely satisfied. In case II we might expect the hydroxyl group on one side and the oxygen on the other to possess definite stray fields of force or residual valence. On this basis I and III should give results for work of adhesion which fit in together whereas the α odd acids as shown by case II, should show markedly higher values for work of adhesion. This prediction is ful-

¹ J. Chem. Soc., 125, 881 (1924).

filled by the results of Fig. 1. It is therefore felt that the hypothesis of Garner and Randall is well supported by these measurements and their explanation of the cause of the alternation is adopted.

The alternation has therefore seemed to be capable of elucidation. The general trend of the results, however, with a definite minimum in the neighborhood of 13 carbon atoms for the even acids and 12 carbon atoms for the α odd acids, and in particular the marked increase in work of adhesion for the higher acids, is entirely unexpected and difficult to account for. The first part of the curve (Fig. 1) from six to thirteen carbon atoms is in accord with

FIG. 12

what we should expect, it being assumed that an indefinite increase in the length of the inactive portion of the chain would result in fewer molecules being perfectly oriented with carboxyl groups towards the water. This is illustrated in Fig. 11 where the molecules and the carboxyl groups at their ends are shown in a conventional manner. When the molecules are short and have a certain amount of mobility, it is relatively easy for a large number of them to turn their carboxyl groups toward the water. As they increase in length a certain number of them would be likely to lie at such angles that others are prevented from turning their carboxyl groups toward the water. Others may bend over as shown by the lower figure, producing the same effect. The net result is that a smaller number of carboxyl groups come in contact with water and there is consequently lower work of adhesion. This crude mechanical explanation immediately falls down after we pass the minimum point.

A hypothesis of a purely speculative nature has been suggested to the writer by Dr. E. K. Carver. Use has been made of the energy-temperature relation in an attempt to construct a picture satisfying the requirements. A diagram for total adhesional energy and free adhesional energy against

temperature can be drawn in a manner exactly analogous to the relations for total surface energy and free surface energy. Harkins and his collaborators have shown that, like total surface energy of a liquid, the total adhesional energy, over a certain range, is independent of the temperature, probably in a manner similar to the former. They have further shown that the free adhesional energy or work of adhesion varies with the temperature very similarly to the free surface energy or surface tension of a liquid. It therefore seems quite correct to construct the diagram as indicated.

Unfortunately, any data which might be of help in establishing or refuting this hypothesis, are lacking. The precision of contact angle measurements

FIG. 13

is not yet great enough to allow the measurement of the temperature coefficient of the adhesional work. This has been done by Harkins for a number of liquids but the measurement of liquid interfacial tensions can be made many times more precise than can the results for contact angles of solids, where many uncertain factors are involved. Consequently, we are unable to indicate from experimental data the exact nature of the energy-temperature relation. Fig. 12 represents a family of curves drawn entirely on an arbitrary basis and representing really only a pure guess as to possible relations. The upper set of curves represents the total adhesional energy for successive or regularly increasing homologues. The other set of curves joining the extreme ends of the first set shows the relations for the free adhesional energy. If we now take a cross-section of the latter set of curves at the point shown by the vertical line, the values of the free adhesional energy or work of adhesion show a relation with the number of carbon atoms indicated in Fig. 13. This is a curve having a minimum point bearing some resemblance to the results shown in Fig. 1.

This hypothesis has not as yet been fully developed and admittedly lacks experimental evidence. It would seem also to be scarcely sufficient to explain alone the general trend of the results for the fatty acids. Nevertheless, it is

felt that the explanation just suggested is at least in part correct and is partially responsible for the great change in work of adhesion with number of carbon atoms.

It is believed that the effect of the length of the chain must in some part be responsible for the results obtained. The short chain acids are more polar than the long chain acids—that is, the carboxyl group seems to possess a stronger residual valence when attached to relatively few methylene groups. The short chain acids, for example, possess higher solubility and are much more strongly acid. For purely mechanical reasons, these short molecules are also able to orient themselves with much greater ease. A large number therefore will be oriented with their carboxyl groups in the same direction.

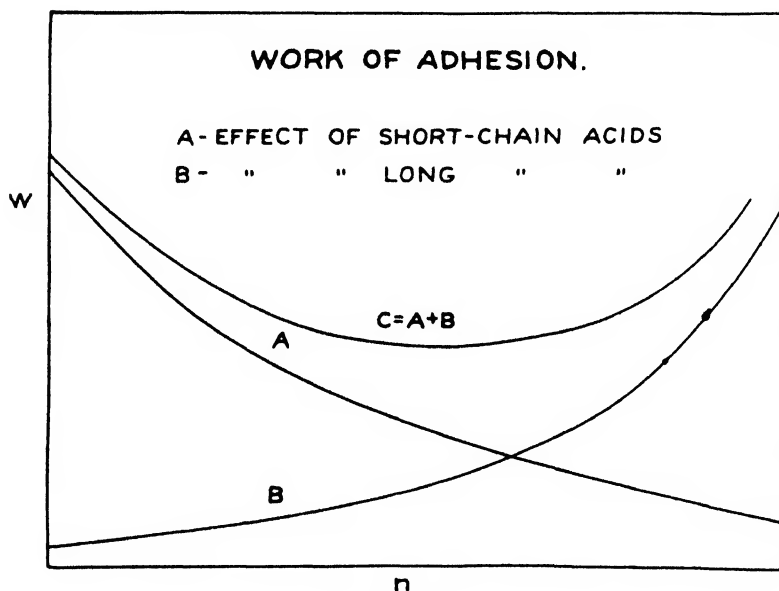

FIG. 14

As the length of the chain increases, the ease of orientation decreases and the consequent effect on the work of adhesion may be roughly indicated by Curve A, Fig. 14.

At the same time as the chains increase in length there are two effects which will tend to keep the molecules in place once they are oriented. The first of these is the mechanical effect of the long chain making it more difficult for the molecule to move about or turn and the second is the mutual attraction of the methylene groups for each other producing the same result. Consequently, as the number of carbon atoms increase we shall have a gradual increase in the number of molecules which are oriented and remain so, and this effect may be represented by Curve B, Fig. 14. The net result of the two effects shown by Curves A and B will be a curve of the shape shown in Curve C. It is seen that Curve C, Fig. 14, and the curve of Fig. 13, are both

in the direction of the general results for work of adhesion shown in Fig. 1. It is therefore believed that both effects are jointly responsible for the shape of the latter curve.

Summary

1. When work of adhesion of the fatty acids is plotted against number of carbon atoms, the adhesional work shows a marked minimum in the neighborhood of 12 to 14 carbon atoms, beyond which there is a very pronounced increase.
2. The alternating effect shown by odd and even acids is very marked, the odd acids showing two enantiotropic forms. The β odd and even acids lie on a single smooth curve, the α odd modifications showing alternating higher values.
3. The alternation and two sets of values for α and β odd acids are attributed to differences in crystal structure. (See Fig. 10)
4. The general trend of the curve for adhesional work against number of carbon atoms is considered as partly due to the general nature of the adhesional energy-temperature relations and partly to the mechanical effects of the length of the carbon chain.

CATALYTIC REDUCTION OF NITRO-ORGANIC COMPOUNDS IN THE LIQUID SYSTEM

BY O. W. BROWN, G. ETZEL AND C. O. HENKE

Introduction

In this investigation a study of the catalytic reduction of nitro-compounds in the liquid phase was undertaken. The compounds reduced were: nitrobenzene, α -nitronaphthalene, p-nitrotoluene, o-nitrophenol, p-nitrophenol and di-nitro toluene. The reductions were carried out with a nickel catalyst, in a hydrogen atmosphere under a pressure of 200 to 700 pounds per square

FIG. 1

- A—Autoclave proper, capacity 80 cc., tested for 3000 lbs. per sq. in.
- B—Six in. piece $\frac{1}{2}$ in. rigid hydraulic iron pipe.
- C—Union.
- D—Eight ft. piece $\frac{1}{2}$ in. flexible copper hydraulic pipe.
- E—One-half in. elbow.
- G—Support to attach apparatus to the ceiling of the room.
- H—One-fourth in. steel wire.
- I—Four ft. piece $\frac{1}{2}$ in. hydraulic iron pipe.
- L—"T".
- M—One-half in. nipple 3 in. long.
- N—One-half in. nipple one foot long.
- K—One-half in. hydraulic iron pipe one ft. long.

- Q—Hydrogen tank, 200 cu. ft. capacity.
- R—Hydrogen pressure gauge.

inch ($15\frac{1}{2}$ to $47\frac{1}{2}$ atmospheres). In order to insure intimate contact between hydrogen, catalyst, and nitro compound, the mixture was agitated

vigorously by shaking. The variable factors studied were: temperature, pressure, amount of catalyst, time of reduction and kind of solvent used.

Borchet¹ states that he has carried out the reduction of some nitro-organic compounds in the liquid phase with a nickel catalyst. A. N. Parret and A. Lowry² have studied the catalytic reduction of α -nitronaphthalene with hydrogen under pressure in presence of a nickel catalyst.

Apparatus

The apparatus used in this investigation was designed by O. W. Brown and C. O. Henke. Fig. 1 shows the apparatus.

The autoclave was shaken by means of an eccentric arm which had a stroke of two in. and was driven by a 1/6 horse power electric motor. Pipe B was threaded to the upper part of the autoclave. The autoclave proper was connected to the autoclave cover by means of six bolts, $\frac{1}{2}$ in. in diameter, S.A.E. threads. The flexible copper pipe D was looped once at S. This loop takes care of the backward and forward movement caused by the eccentric arm. The junction between the cover and the autoclave was sealed by means of a lead gasket.

Heating Element

The heating element consisted of an electric heating jacket. It was made by wrapping asbestos paper around a strong tin can. Then about six turns of No. 18 chromel wire were wrapped around the paper, and the whole covered with more asbestos paper. The ends of the wire were doubled and twisted tightly in order to insure greater strength.

Method of Procedure

Known weights of organic compound and of reduced nickel catalyst were placed in the autoclave, and a definite amount of solvent added. A slow current of hydrogen was passed thru the pipes to wash out all air while the autoclave was being bolted to its cover. The bolts were then tightened and the hydrogen pressure was turned from the large tank until the required pressure was reached. The large tank was then closed. The autoclave was then immersed in water to test for leakage. The purpose of the small tank was to act as a reservoir and to insure an uniform pressure during the reduction period.

The heating jacket was placed in position around the autoclave and connected to a source of current (110 volt).

The temperature of the reaction mixture was determined by means of a thermocouple which was inserted into a hole drilled into the wall of the autoclave. This hole was a $\frac{1}{8}$ in. in diameter bore from one side to the center of the bottom of autoclave. The point at which the temperature was taken was $\frac{3}{8}$ in. above the outer bottom surface of the autoclave and about one in. below the reacting chamber. An iron collar was used to hook the eccentric

¹ Brochet: Bull., (4) 13, 197 (1913); 15, 554 (1914).

² A. N. Parret and A. Lowry: J. Am. Chem. Soc., 48, 778-782 (1926).

arm to the autoclave. A hole was left in the heating jacket for the insertion of the eccentric arm. The temperature required was obtained by adjusting an external resistance.

When the desired temperature was reached the motor was started and the apparatus shaken for a definite period of time, usually two hours, at 150 R.P. M. At the end of this time the heating jacket was removed, the small tank closed, and the autoclave cooled by surrounding with cold water. The hydrogen pressure in the autoclave was allowed to escape thru the gauge.

The autoclave was then opened, the contents examined as to color and odor. It was poured into a two-liter beaker containing 50 cc. of concentrated hydrochloric acid. The autoclave and the lower end of the pipes were carefully washed with alcohol. The hydrochloric acid solution was diluted to two liters, mixed, and portions titrated against a standard solution of sodium nitrite.

Preparation of Catalyst

The nickel catalyst was prepared by igniting the nitrate and then reducing the oxide in hydrogen. The nitrate, with a small addition of nitric acid was ignited in a small porcelain evaporating dish in an electrically heated muffle. The temperature of ignition was measured by a copper constantan thermocouple, the junction being in the dish just above the nickel oxide. The nickel oxide, after cooling, was powdered and put in the furnace as described by Brown and Henke.¹

The temperature of ignition of the nitrate was 560°C. The oxide was reduced at a temperature of 378°C with the rate of flow of hydrogen 14 liters per hour.

Material Used

Nitrobenzene used was purified by shaking it with sodium carbonate solution and then steam-distilling it. The distillate was dried with calcium chloride and then redistilled twice. The hydrogen used for reduction was commercial hydrogen. The α -nitronaphthalene used was a C.P. product from Eastman Kodak Co.

Experimental Part

A series of experiments was first made to ascertain the best temperature and pressure. The amount of nitrobenzene used in each experiment was 4.7354 g. The amount of benzol, which was used as a solvent, was 8 cc. Results obtained are given in Table I.

TABLE I

Amount of reduced nickel catalyst			2.5 g.		
Time of reaction			2 hrs.		
Temperature C	Pressure lbs. per sq. in.	Amine % of theory	Temperature C	Pressure lbs. per sq. in.	Amine % of theory
190	500	99.05	215	200	25.04
215	500	100.03	215	300	67.45
253	500	95.54	215	500	100.03
282	500	52.53	215	700	100.

¹ Brown and Henke: J. Phys. Chem., 26, 161-190 (1922).

The experiments of Table I indicate that 215°C is the best temperature for the reduction when a pressure of 500 lbs. is used. By changing the temperature 20°C above or below 215°C the yields vary slightly, while by a constant increase they suddenly drop. By varying the pressure and keeping the other factors constant we notice that as the pressure increases the yields increase, 500 lbs. per sq. in. giving a quantitative reduction.

Table II gives the results of a study of the variation of the amount of catalyst and time of reaction.

TABLE II

Amount of Catalyst g.	Temperature Pressure Solvent Benzol	Time of Reaction minutes	215°C 500 lbs. 8 cc.	Amine % of theory
2.5		15		3.96
2.5		30		93.21
2.5		60		99.21
2.5		120		100.3
1.		120		43.42
.1		120		16.06

Experiments described in Table II show that the maximum yields were obtained when the reaction was allowed to take place for the period of two hours, although a good yield was obtained when the period was one hour. Two and one half grams of catalyst for 4.7354 g. of nitrobenzene gave the best results. The yields decreased quite rapidly with a decrease in the amount of catalyst.

Effects of different solvents on reduction of nitrobenzene were tried. The results are shown in Table III.

TABLE III

Solvent Used	Amount of Solvent cc.	Amine % of theory
None	—	99.94
Benzol	8	100.03
Absolute Alcohol	8	99.78

It is seen from Table III that quantitative yields were obtained with or without solvent.

A few experiments were carried out on the reduction of α -nitronaphthalene to α -naphthylamine at a pressure of 500 lbs. A. N. Parret and A. Lowy¹ reduced this same compound using a pressure of 50 to 100 lbs. and ob-

¹ A. N. Parret and A. Lowy: J. Am. Chem. Soc., 48, 778-782 (1926).

tained with nickel catalyst a maximum yield of 70%. The results obtained by the writers are given in Table IV.

TABLE IV

Temperature		215°C
Pressure		500 lbs.
Amount of catalyst		2.5 g.
Amount of α -nitronaphthalene		4 g.
Time of reaction		2 hrs.
Solvent	Amount of Solvent cc.	Amine % of Theory
Benzol	8	99.55
Ethylene Glycol	10	89.78
Ethyl Alcohol	10	98.31

Better yields were obtained with benzol as solvent than with either ethyl alcohol or glycol. The latter was the poorest. Brown, Henke and O. C. Criswell reduced in this laboratory *p*-nitrotoluene, with a pressure of 500 lbs. per sq. in. and 215°C. A quantitative reduction was obtained. *O*-nitrophenol *p*-nitrophenol and di-nitrotoluene were also quantitatively reduced. The conditions were as follows: temperature 226°C, pressure 500 lbs. per sq. in., solvent used absolute alcohol, catalyst nickel made by reducing nickel carbonate at 378°C.

Conclusions

1. Experiments were conducted showing that liquid nitrocompounds and nitrocompounds in suitable solvents can be reduced quantitatively to amines, with hydrogen under pressure, and with a nickel catalyst.
2. Quantitative reduction of nitrobenzene, α -nitronaphthalene, *p*-nitrotoluene, *o*-nitrophenol, and di-nitrotoluene was obtained at 215°C and at a pressure of 500 lbs. per sq. in.
3. For the best results 0.52 g. of nickel catalyst was required for each gram of nitrocompound reduced.
4. Benzol and ethyl alcohol were solvents that permitted quantitative reduction of nitrocompounds studied.

NEW BOOKS

Pyrometry. By W. P. Wood and J. M. Cork. 23 × 16 cm; pp. viii + 207. New York and London: McGraw-Hill Book Company, 1927. Price \$3.00. In the preface the authors say, p. v.: "while there are a few reference books on pyrometry there is no work which is organized in such a manner as to be of great utility as a textbook for college students. Instructors have been forced to handle the subject entirely by lecture or by personally prepared sets of notes. This manuscript, therefore, has been assembled with the needs in mind of the student as well as of the man more experienced in the uses and the theory of pyrometry. Questions and problems are added at the end of some of the chapters. Outlines for laboratory experiments are included. These are largely suggestive and may be modified to meet local conditions."

The headings of the chapters are: temperature scales; fluid thermometers; thermo-electric pyrometers; resistance thermometers, optical pyrometers; total radiation pyrometers; temperature recorders and controlling devices; transition points and thermal analysis; refractory materials used in pyrometry.

"Most gases obey Boyle's law very closely at temperatures distant from their condensation points. When used for temperatures close to the condensation point, the error in the normal thermometer is surprisingly small. Kammerlingh Onnes tested this effect by comparing a hydrogen thermometer with a helium thermometer at temperatures close to the condensation point of hydrogen and found that the error was negligible when distant from the condensation point by 0.5°. . . . The hydrogen thermometer deviates 0.005° from the thermodynamic scale at -100° and 0.004° at +1000°," p. 13.

"The fact that the gas scale is fundamental by agreement should not be overlooked, however, and since it has not been used above 1550°C., higher temperatures can only be measured by extrapolating certain laws which have been found to hold true below this value. Hence for these higher temperatures, an element of uncertainty exists and it is only by extrapolating with several different laws, which have been independently verified in the known region, and by obtaining in each case the same value at the higher temperature that confidence is placed in the result. The uncertainty attendant upon extrapolations of this sort is well illustrated by the following early experiment in high-temperature measurement carried out by Wedgwood. He attempted to measure temperature by the shrinkage caused by that temperature upon a certain sample of clay. The measuring of the shrinkage for the known temperature interval from the freezing to the boiling point of water sufficed for a calibration of the instrument. By comparing this shrinkage with that which took place when the clay was placed in a furnace at the temperature of melting iron, he expressed the melting point of iron as about 12000° C., a value about 10500° too large," p. 16.

"The length of the couple which lies within the heated zone is of great importance. This is sometimes called the "depth of immersion." If a couple is insufficiently immersed, conduction to the outer, cooler sections is so high that the reading of the couple will be low. It is a good practice to insert the couple just as far as possible. This will insure satisfactory results as a rule, but in cases where it is suspected that the immersion is not sufficient, the temperatures along the protecting tube should be explored and if there is a sudden drop near the hot end of the couple, means should be taken to produce a sufficient immersion.

"Some couples are purposely immersed an insufficient distance. This is done when the temperature of the furnace is so high that there is danger of fusing the couple and tube. Although the temperature read is low, it is possible, by correlation with physical changes of material within the furnace, to obtain a fairly accurate idea of the temperature for future operations," p. 60.

"The assumptions made in the development of Planck's formula led to the now famous quantum theory. Many precise experiments have been made to test the validity of this

equation and the conclusion seems to be that it fits the experimental facts very closely throughout the entire wave-length range for the temperatures used in the experiments, which have been from 400 to about 1500°C," p. 85.

"In an optical pyrometer, brightness match is obtained between the filament and the image formed by the objective, regardless of the history of the radiation before coming to the objective. The radiation might, therefore, come from a reflecting surface which is itself cold. The apparent temperature of the body would in this case be much greater than its true temperature. For example, a wall in sunlight might have an apparent temperature of 2000°C. Hence, care must be taken that the body whose temperature is being determined is not reflecting radiation from another bright source," p. 104.

"In a progress report on optical pyrometry recently published, many of the following remarks are included: optical pyrometry has grown to mean almost exclusively high-temperature measurements with the disappearing-filament type of pyrometer. This type is simple in construction, affords great accuracy and is adapted to a diversity of conditions. While the optical pyrometer may still be regarded as a secondary device, so much experimental confirmation of the quantum theory and consistent experimental values of the radiation constants have been obtained that it seems reasonable to make use of it in checking the high-temperature gas scale. The precision, accuracy and wide range of usefulness of the disappearing-filament optical pyrometer depend on perfect disappearance of the filament with high resolving power and magnification by the eyepiece. By designing the instrument to avoid diffraction effects, Fairchild and Hoover state that it is possible to obtain a precision of 0.2°C. or better at the melting point of gold. To test the consistency of the high temperature scales in use in various research laboratories in this country and England, Forsythe recently compared the current-temperature relations for certain lamps found in these various laboratories. These high-temperature scales are based upon assumptions regarding the melting point of a metal and a value of the c_2 radiation constant. Thus the basis of the scale at the General Electric Research Laboratory and the U. S. Bureau of Standards is $c_2 = 14,350$ and the melting point of gold, 1063°C. At the National Physical Laboratory, England, $c_2 = 14,350$ and the melting point of palladium, 1555°C. The agreement of the scales was found to be very good, differences being only a few degrees over the range from 1000 to 2400°C," p. 108.

"An objection to an instrument of the total-radiation type arises from the fact that the objective lens, if made of glass, absorbs a large part of the radiation incident upon it, especially in the infra-red spectral region. Since most of the radiant energy from bodies at temperatures not exceedingly high lies in the infra-red region, the sensitivity of the apparatus is greatly reduced. Further, the fourth-power law or any other simple expression does not apply to the radiation transmitted by the glass lenses. Fluorite (calcium fluoride) has a remarkably small and almost constant absorption coefficient for all wave-lengths up to 10 μ , and would be a suitable material from which to make the lenses of the instrument. Its use, however, is limited by its expense. To overcome this objection Féry in 1904 suggested the use of a concave mirror similar to the astronomical reflector to replace the lenses," p. 116.

Wilder D. Bancroft

The Electronic Theory of Valency. By Nevil V. Sidgwick. 24 × 16 cm; pp. xi + 310. London and New York: Oxford University Press, 1927. Price: 15 shillings; \$5.00. This book is uniform with the recent books in the same series by Hinshelwood and by Paneth and Hevesy; it is excellently produced, but is still sufficiently expensive in this country to make it worth while to place one's order in England.

In the case of the compounds of one of his elements, carbon, the chemist has, in part at least, succeeded in bringing order out of chaos, and the resulting system is the realm of organic chemistry. In the realm of inorganic chemistry, however, the chemist is still oppressed by a heterogeneous collection of disorderly facts. The timely and very welcome volume before us helps to keep alive the hope that, in the not too distant future, the in-

organic chemist may be able to show that, by a deductive method, his myriad molecules with their properties and reactions are entirely predicable from a knowledge of the relatively small number of chemical atoms that enter into them.

In developing the theory of valency, Professor Sidgwick adopts the concepts of atomic physics, and tries to explain the chemical facts in terms of these; realising however, as certain others have failed to do, that one should not use the terminology of physics unless one is prepared to recognise its laws. Writing today, the author of a book on the *electronic* theory of valency must needs anticipate the criticism that the newer wave mechanics has already dissolved, or at least sadly attenuated, the so-called electron. Professor Sidgwick meets this criticism in his preface, as Sommerfeld, Richardson and others have done before him.

The earlier chapters deal very concisely with atomic structure and lead up to a table of structures compiled with help from Dr. Stoner. "Subgroups" and "grouplets" are here carefully distinguished with reference to the k and j quantum numbers, because, of necessity, use is later made of these terms,—terms which were unknown when G. N. Lewis's book on valency was published.

As was to be expected, in developing the fundamental principles of valency a very clear presentation is given of what Sidgwick has called the "coordinate link." For the past few years the reviewer has devoted two or three lectures annually to Sugden's parachor. Here for the first time to his knowledge the parachor is discussed in a textbook, and used, of course, in evidence for the coordinating linkage. Using the nomenclature which he suggested at the 1927 meeting of the British Association, Sidgwick distinguishes "donor" from "acceptor" atoms, terms which prove useful in discussing—without diagrams the chelate rings of Morgan, associated liquids and other topics. Another Sidgwickian contribution is dealt with in the chapter on covalency maxima. Does the famous octet still survive? Yes, most certainly, but it is no longer all-important. How do we now explain the substantial fact that carbon and silicon, so closely analogous in their hydrogen and halogen compounds, are so radically unlike in their dioxides? Lewis suggested that silicon, being an element beyond the second period, could not form double bonds; Sidgwick suggests that, by the covalency maximum rule, the maximum covalence of the second period element carbon cannot exceed four, whereas a third period element like silicon may have a covalence of six. The concepts of "pure" or "mixed valency groups" and of "effective atomic number" help the author to catalogue and classify the valency groups which, in practice, are found to be stable; and the last named conception helps to make clear the wonderful promise of work like that of Welo and Baudisch on paramagnetism in complexes.

Aside from his own contributions, other people's ideas are very clearly presented in the discussions on solubility, solvation, Werner's theory of coordination, Fajans' valence theory, molecular magnetism, stereochemical relations and chelate rings. It is vastly convenient to have so many relevant modern ideas marshalled together in a well-digested form.

The book closes with a systematic study of the periodic groups in the light of the discussion that has gone before, involving some repetition of this but also some anticipation of the material of a second volume which the author promises and to which everyone who has read this first volume must look forward with pleasure.

The attention of the author will be drawn to any errors or obscurities that have met the observation of the group of over a dozen graduate students with whom the reviewer has gone over the book. These errors and obscurities are few in number. At many points, there is room for difference of opinion; and this is what makes the book stimulating. For example, Sidgwick refuses to go as far as Sugden in the matter of single electron bonds, but he boldly tells us the facts as to bivalent hydrogen, and this is very wholesome for the souls of the conservative.

We owe a debt of gratitude to Professor Sidgwick for this scholarly and inspiring book.

Alan W. C. Mensies

The Theory of Strong Electrolytes. *A General Discussion held by the Faraday Society, April, 1927.* 24.5 × 15.3 cm; pp. iv + 212. London, 1927. Price: 15s. 6d. The Faraday Society has in the past rendered valuable services to Physical Chemistry, not only by the publication of its *Journal*, which now appears monthly and promises to become ever more useful, but also in the promotion of a series of highly successful general discussions on matters of current interest. The present volume, containing an account of a recent discussion, is in every way worthy of its predecessors. A comparison of its contents with those of the volume containing the discussion on "Electrolytic Dissociation" which appeared in 1919 will show how the subject has advanced since that date. The present volume lacks a general account of the whole discussion, in which the various points of view are co-ordinated and any new ideas or experiments are emphasized. It is to be hoped that future discussions will always be accompanied by such a summary. Much of the material in the volume is in no way new and some of it (especially in the parts dealing with activity) has appeared many times before, so that some little difficulty may be found in ascertaining what is presented for the first time. The volume is divided into two parts, one dealing with the Mobilities of Ions and the other with Activities. In the first part Debye gives a summary of the assumptions underlying his theory, and this is followed by a paper by Onsager in which some corrections which he has introduced into Debye's theory to take account of the Brownian movements of the ions are explained. The new equations give more satisfactory results than the older ones, but they apply only at high dilutions. In moderately concentrated solutions the difficulty as to the precise form which the viscosity correction (which is apparently regarded as necessary) takes was felt by several authors. This is one of the problems awaiting a satisfactory solution.

It is clear from the results quoted in several papers that the initial hypothesis of complete ionisation, which seemed to many to be so well established a year or two ago, will require modification. An "association" of the ions is necessary in many cases even when the concentrations are not high, and there are papers by Fajans, Ferguson and Vogel and MacInnes and Cowperthwaite in which the hypothesis of complete ionisation is attacked on experimental grounds, although the validity of Fajans' arguments was called in question. Onsager points out that in his theory the coefficient of the concentration term may be calculated from the mobilities without any assumptions as to the ionic radii, and it should then be possible to determine the effects of other than electrical forces, for example "association." This is attempted by Hartley and Bell, but these authors have made use of the unmodified Debye formula and their results are, therefore, not free from ambiguity.

A communication from Remy deals with "true" transport numbers (corrected for the transport of water), and there are papers by Ulich and by Hartley and Raikes on mobilities in non-aqueous solvents. Very little new experimental work is brought forward in these papers.

Part Two deals with activity. Much familiar ground is retraversed in this part but the section is enlivened by no fewer than seven experimental papers. Brönsted, Randall, and Harned contribute general articles on the activity of strong electrolytes, including concentrated solutions. Kraus and Seward and King and Partington describe experiments on the influence of one salt on the solubility of another in non-aqueous solutions. Kraus and Seward conclude that the effects are not satisfactorily accounted for on the basis of the Debye theory and that "there are not a few facts that indicate that in solvents of lower dielectric constant it will be necessary to let fall the assumption that the only molecular species present are the simple ions." There are theoretical papers by Bjerrum, Chapman, Fowler, Scatchard, Allmand and Lowry. Bjerrum deals with the interesting problem of heats of solution, which has very recently received attention elsewhere with conflicting results. Allmand and Burrage, Foxton and Shutton and Millet contribute accounts of experiments on the system $\text{KCl-PbCl}_2\text{-H}_2\text{O}$, on the activity of ZnCl_2 in concentrated solution (a problem which, it may be mentioned, was one of the first to be dealt with in the study of the thermodynamics of solutions), and on the activity of the hydrogen ion in mixed solvents, respectively. The volume closes with a brief discussion and an index.

Although no new fundamental addition to the theory of strong electrolytes was made during the discussion, the summary of present views, and suggestions as to their probable modification with the advance of experimental knowledge, is useful, and the volume may be recommended as one which most physical chemists will be well advised to possess.

J. R. Partington.

Les Origines de la Chimie colloïdale. By Paul Bary. 20 × 13 cm; pp. 78. Paris: *L'Expansion Scientifique*. Price: 6 francs. The French chemists have rediscovered Baudrimont in a rather interesting way. Some years ago Mr. W. A. Bender, chief chemist of what is now the Certo Corporation, called the reviewer's attention to the fact that Baudrimont had published some very good work on colloid chemistry in 1844-1846, long before Graham. The reviewer published a short note on the subject and the information it contained was apparently as new in France as it was in America.

M. Bary has now published a very welcome biographical sketch of Baudrimont who was a remarkable man in many ways, besides being a man who never missed a fight even if he had to start it himself. According to Baudrimont's own classification he published articles on: the philosophy of science; crystallography, atoms, and the structure of substances; cosmology and cosmic dynamics; general physics; chemistry; physics; mechanics; anatomy and general physiology; human physiology; vegetable physiology; medicine, pathology, pharmacology, and therapeutics; geology, mineralogy, and meteorology; agrolgy; industry; social economics; mathematics; philology; education; pyrotechnics and ballistics; miscellaneous.

According to Baudrimont this was a very easy matter. One can master any subject in two years and consequently twenty subjects will only take forty years. This would be simple enough if one did not have to earn his own living; but Baudrimont did have to, so one must consider this showing as remarkable. Of course Herbert Spencer did something similar; but he is recognized as having been a remarkable man.

Before he was thirty, Baudrimont published a book entitled "Introduction à l'Etude de la Chimie par la théorie atomique;" but this was considered so revolutionary that he was forced to leave the Collège de France where Thénard had given him a position. In 1838 Baudrimont became a candidate for the chair of chemistry in the school of pharmacy, his chief opponent being Dumas. Baudrimont's criticism of Dumas' topic was so scarifying that it prevented Baudrimont from getting any chair in Paris either then or later and he was forced eventually to accept a call to Bordeaux where he remained the rest of his life.

The latter part of this pamphlet is taken up with extracts from the works of Baudrimont, a very desirable thing because the originals are scarcely accessible. Wilder D. Bancroft

Annual Survey of American Chemistry. Vol. II. Edited by Clarence J. West. 22 × 14 cm; pp. 415. New York: The Chemical Catalog Company, 1927. Price: \$3.00. The first volume was criticized rather severely last year by the reviewer (31, 1278). The same remarks apply to this volume and there are now more people who share the reviewer's viewpoint. Unless these volumes are changed radically, it will not be long before everybody will be apologizing for them. The individual writers have been selected with care and have done their thankless tasks as well as could be expected.

The reviewer was much interested in the paragraph by Withrow, p. 115. "One of the most interesting achievements which have come to the attention of the writer during the year has been the manufacture of smoked salt. The salt used in pickling is smoked before use in pickling meat, thereby securing a greater penetration of smoke ingredients into the meat than in the normal practice of true smoking. It looks as though a revolutionary improvement in meat "smoking" were thus available. The product of this process when properly conducted has a golden brown color with a delicious smoked bacon or ham odor and taste. It can be readily distinguished in many ways and particularly by its odor and taste from numerous substitutes already appearing on the market which consist merely of salt treated with a filtered pyroligneous acid, followed by drying or evaporation. Contrary to superficial expectation the two products are not at all alike even in flavor. The manufacture of true "smoked salt" as distinguished from the imitation "smoked-salt" has reached a production amounting to many thousands of tons and is a rapidly growing business."

Wilder D. Bancroft

THE DETERMINATION OF THE ζ -POTENTIAL ON CELLULOSE.— A METHOD*

BY DAVID R. BRIGGS

Electrokinetic Phenomena

The colloid electrical effects were named by Freundlich¹ "electrokinetic phenomena," to distinguish them from a kindred though not determinate phenomenon, the "thermodynamic potential," which exists also across the interface.

The electrokinetic properties are very closely related to other colloid properties. Adsorption, interfacial tension, flocculation, etc., are kindred phenomena and may, at least in some instances, be partially explained in terms of the electrical potential difference existing at the interface, and of which the electrokinetic phenomena are a means for measurement. Freundlich² has shown recently that such measurements, which deal with the so-called ζ -potential, do not tell the whole story. As will be pointed out later, the ζ -potential measurements may not deal with the actual interface primarily, but with the fixed and movable layers of one of the phases in the immediate environment of the interface. However, the conditions extant in the interface will have in most cases, a determining influence upon these so closely adjacent layers, and we may reasonably expect to find significant differences by the utilization of these measurements, which are as fundamental, and probably more so, as are those obtained from adsorption measurements.

The more common methods for determining the charge on a colloidal particle are by means of the cataphoresis and electrosmosis phenomena. These methods are well known and have been utilized extensively for comparative measurements of the charge on such various colloidal materials as are readily adaptable to the conditions of such experiments. After considerable experimental investigation, it was found that to use either method for measuring the ζ -potential on cellulose would be undesirable.

Kruyt³ and Freundlich³ and Rona have recently published papers describing their determinations of the ζ -potentials on capillary glass tubes by the streaming-potential method, wherein a liquid was forced through the tube under a measured hydrostatic pressure and the electromotive force set up across the tube was measured by potentiometric means. They found that the observed electromotive force was independent of the area of cross section or length of

*Contribution from the Division of Agricultural Biochemistry, University of Minnesota. Published with the approval of the Director, as Paper No. 745, Journal Series, Minnesota Agricultural Experimental Station. Revised from a thesis presented by David R. Briggs to the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the Degree of Doctor of Philosophy, June, 1927, R. A. Gortner, thesis adviser.

the tube. For a given liquid, the electromotive force observed, varied directly with the hydrostatic pressure and varied with the kind of glass, but *was constant for all sizes and shapes of tubes prepared from the same sample of glass*. It is by an adaptation of this method, modified to make possible its use on materials of such nature as paper pulp, that the measurements upon which the present paper is based were made.

The charge on a colloid is due to the presence of an electrical double layer in which, we must assume, "the electrical forces are arranged in equilibrium with osmotic or other forces present, so as to be a minimum." Michaelis^{4, 5} considers that there are three fundamental sources of this electrical double layer. Two are to be considered as examples of the action of forces with which we are familiar elsewhere in chemistry and physics. First, the forces of residual valencies which cause oriented adsorption, and second, the forces of dissociation which cause exchange adsorption. The third, Michaelis says, is due to the spontaneous distribution of ions at the free surface and comes into play in those cases where the electrical double layer is set up at the boundary of substances which are totally unreactive chemically, and are incapable of dissociation.

An example of the first case is that of AgI precipitated in an excess of either the Ag^+ or I^- ions. The surface valencies of the crystals are unsatisfied. There are both Ag and I atoms on the surface, and these will show a selective attraction for ions of opposite charge in solution, and the crystal will thus take on a positive or negative charge depending upon which ion, Ag or I, may be in excess in the solution. The iso-electric point need not be at the point of exact neutralization of Ag^+ and I^- ions in solution, however.

Of the second type, i.e., exchange adsorption, "there is a large number of evidently heteropolar compounds, peculiarly prone to electrolytic dissociation, in which one of the ions resulting from the dissociation is incapable of existence in the molecularly dispersed dissolved state." An example is silicic acid or a silicate. With silicic acid the dissociation tendency is the same as with any acid; however, the silicate ion does not disperse, but remains bound to the colloidal aggregate. The potential difference across the interface is a result of, and will be proportionate to, the dissociation tendency. (The degree of this tendency to dissociate depends upon the "intrinsic" natures of the solid material and of the liquid phase.)

The third class is illustrated by substances such as cellulose, collodion, or air bubbles. In these substances there is no oriented adsorption, nor is there a tendency to dissociate (certainly true in case of air bubbles). Yet a charge exists at the interface of these substances. This Michaelis explains as due to a difference in the capillary activity of H^+ and OH^- ions. He assumes that the OH^- is more capillary active than the H^+ ions and, therefore, the OH^- enters closer to the actual surface than the H^+ , thereby creating a zone of potential difference.

⁴ Michaelis: p. 471, "Colloid Chemistry," edited by J. Alexander (1926).

⁵ Michaelis: "Effects of Ions in Colloid Systems," (1925).

The characteristic features of "electrokinetic phenomena" are those of a heterogeneous system, one phase of which must be liquid and, in which, relative mechanical motion occurs between the different phases when they are subjected to an electrical field of force; or, when mechanical motion is brought about in either phase, an electrical field of force is set up in the system. To the first category belong the phenomena, *electrosmosis* and *cataphoresis*. In the first case, the liquid moves through a fixed diaphragm, while in the second, the colloidal particle moves through the liquid, under the influence of an electrical field. To the second group belong the *streaming potential* and *migration potential* (potential of falling particles) phenomena, wherein mechanical motion of the liquid or solid phase, respectively, gives rise to an electrical field of force in the system.

That solid materials immersed in water or other liquids show a difference of electrical potential across the interface has long been known. This, in fact, is to be expected from the first law of electrostatics, which states that all bodies coming into contact with each other become oppositely charged with electricity. Reuss⁶ in 1808, observed that when an electric current was passed through an earthenware diaphragm, water was transferred from the anode to the cathode chamber. In 1816, Porret⁷ described the same phenomenon when he used a sand diaphragm. Wiedemann^{8, 9} and Quincke¹⁰ made quantitative measurements of this electro-endosmosis phenomenon, and Quincke first showed that the water might travel in either direction depending upon the nature of the solid used, an observation which led him to the theory of the existence of an electrical double layer across the interface, the sign of which might be differently arranged for different substances. The theory of electrosmosis was first quantitatively expressed by Helmholtz^{11, 12}, and later by Perrin,^{13, 14} by Lamb,¹⁵ and by Smoluchowski¹⁶ without radical change.

Helmholtz developed his equation from the consideration of a single capillary tube of the solid material filled with the liquid and placed in an electrical field. He assumed the electrical double layer coating on the tube to be essentially a condenser, the plates of which were separated by a distance equal to the diameter of one molecule. Perrin¹³, following a suggestion of Pellat, introduced the dielectric constant of the liquid as a factor in the formula and thus made possible the assumption of a greater distance between the layers, than that assumed by Helmholtz.

¹⁶ von Smoluchowski: Bull. Acad. Sci. Cracovie, 1903, 182.

The following development of the electro-endosmosis formula is essentially that given by Perrin. Assume a single capillary acting as a diaphragm, across the ends of which is imposed an electrical potential difference. Further, assume the existence of an electrical double layer along the walls of the capillary, one layer of which is fixed tightly to the solid phase, while the other is located at a distance (δ) from the first, and in the liquid phase, being free to move. When an electrical field is set up due to an applied potential difference at the ends of the capillary, one charge tends to move in one direction, while the other tends to move in the opposite direction. The charge on the solid being fixed, the charged liquid layer will be moved along the surface of the capillary at such a rate that the frictional forces (R) are at equilibrium with the electrical forces (E).

The electrical force (E) acting on unit area of surface equals the product of the charge (e) on the double layer per unit of surface, and the applied potential difference (H) over unit length.

$$E = eH$$

At equilibrium, this must be equal to the frictional force (R) which it has overcome or balanced,

$$R = \Delta\eta,$$

where η = coefficient of viscosity and Δ = the decrease in velocity of flow of the liquid in a direction perpendicular to the wall of the capillary, that is, the average velocity of the layer of liquid taken between the layer of maximum velocity (u) and the layer of no motion, i.e., the fixed surface.

Then $\Delta = u/\delta$ where (δ) = the distance between the fixed and moving layers and

$$R = \eta u/\delta.$$

The maximum velocity (u) will be the velocity at which the liquid leaves the capillary, since the main body of the liquid in the capillary will move at the same rate as the layer near the wall. (u) may be measured then, by measuring the volume flowing in a given time and the diameter (or area of cross section) of the tube. Volume (v) emitted in given time then, is, where (r) is the radius of the capillary,

$$v = \pi r^2 u$$

then

$$R = \eta v/\delta \pi r^2$$

therefore,

$$eH = \eta v/\delta \pi r^2$$

Helmholtz and Perrin regarded the double layers as flat surfaces lying parallel to each other and at a distance apart (δ). These surfaces can, therefore, be thought of as the two plates of a flat condenser. The capacity (C) of a flat condenser is directly proportional to the quantity (Q) of electricity it holds and inversely as the P. D. (ζ) across the plates, i.e., $C = Q/\zeta$. Also, the capacity of a condenser, by a law in physics, is directly proportional

to the dielectric constant (ϵ) of the material separating the plates, and to the area (A) of the plates, and inversely proportional to their distance apart (δ), and to a constant (4π), that is,

$$C = \frac{\epsilon A}{4 \pi \delta}$$

then

$$\frac{Q}{\zeta} = \frac{\epsilon A}{4 \pi \delta} \text{ or } \zeta = \frac{4 \pi \delta Q}{\epsilon A}$$

but

$$Q/A = e, \text{ the charge per unit area.}$$

and

$$\zeta = \frac{4 \pi \delta e}{\epsilon} \text{ or } \pi \delta = \frac{\zeta \epsilon}{4 e}$$

substituting

$$eH = \frac{\eta v 4 e}{\zeta \epsilon r^2}$$

then

$$v = \frac{r^2 \zeta H \epsilon}{4 \eta} \text{ and } \zeta = \frac{4 v \eta}{r^2 H \epsilon}$$

But, in a diaphragm, the area of cross section (q) takes the place of (πr^2) in the capillary, and $r^2 = q/\pi$,
then

$$v = \frac{q \zeta H \epsilon}{4 \pi \eta}$$

and

$$\zeta = \frac{4 \pi v \eta}{q H \epsilon}$$

$H = El$, where E = applied E. M. F. across diaphragm, and l = distance between ends of diaphragm.

$E = iw$, where (i) is the current and (w) the resistance, and $w = l/q\kappa$ where l = length of capillary, q = cross section area, and κ = specific conductivity of the liquid.

Whence,

$$v = \frac{\zeta i \epsilon}{\pi \eta \kappa}$$

and

$$\zeta = \frac{4 \pi \eta \kappa v}{i \epsilon}$$

This equation states that where the electric current (i) is kept constant, the volume of liquid (v) which will flow in a given time through the diaphragm is directly proportional to the ζ -potential across the interface and to the dielectric constant (ϵ) of the liquid and inversely proportional to the viscosity (η) and specific conductivity (κ) of the liquid, but is independent of the area of cross section or length of the capillary.

We may now consider the electromotive forces produced by the flowing of a liquid through a capillary tube or a porous diaphragm. This phenomenon is in a sense the opposite to electrosmosis. In the latter, an external electromotive force causes the flow of water through the fixed diaphragm while in the former, the mechanical flow of water sets up an electromotive force across the two ends of the diaphragm. Beetz¹⁷ gave the name "Strömungsströme" to the electric current so generated, hence came the name "streaming potential" for the E. M. F. observed across the diaphragm under such conditions. This subject has been studied experimentally by Quincke,^{18, 19} Zollner,²⁰ Edlund,^{21, 22} Haga,^{23, 24} Clark,²⁵ Dorn,²⁶ and Elster,²⁷ the general observation being that the E. M. F. obtained was proportional to the pressure applied. The phenomenon is ascribed as due to a kind of electrical convection, and to be the result of the electrified layer of the liquid carrying its charge along with it as it moves through the capillary. In the case of a straight capillary, this results in a difference of potential becoming manifest at the two ends of the tube, which is compensated, if by no other means, by conduction backwards through the column of liquid in the tube. The simplest example of streaming potential is that in which a liquid is streamed past one electrode immersed in the liquid, while no motion of the liquid occurs around the other electrode.

Helmholtz¹¹ in his well known paper on interface potentials, first treated the subject mathematically. The following derivation of the streaming potential formula is that given by him.

He again considers the simpler case of a single tube filled with a liquid which is being forced through the tube under a hydrostatic pressure and across the interface, solid-liquid, of which there exists a potential difference. Let (e) denote the electrical density of the movable layer at a distance (δ) from the wall of the tube. The value of the velocity of motion (μ) of the liquid at the wall of the tube being zero, then the value of (μ) at the distance (δ) will equal

$$\mu = \partial\mu/\partial\delta \cdot \delta,$$

the infinitesimal rate of change of velocity with the distance component perpendicular to the wall, times this distance. The amount of electricity which is carried along by the liquid in unit time in the surface element ds . $d\delta$ then will be

$$E_0 = e \cdot \partial\mu/\partial\delta \cdot \delta \cdot ds \cdot d\delta$$

Integrating a part of the expression through δ —

²³ Haga: Wied. Ann., 2, 326 (1877).

²⁴ Haga: Wied. Ann., 5, 287 (1878).

²⁵ Clark: Wied. Ann., 2, 335 (1877).

²⁶ Dorn: Wied. Ann., 10, 46 (1880).

²⁷ Elster: Wied. Ann., 6, 553 (1879).

$$\int e \cdot \delta \cdot d\delta = -1/4\pi \int_0^\infty \partial^2 \phi / \partial \delta^2 = 1/4\pi (\phi_i - \phi_s) \text{ or } 1/4\pi \cdot \zeta$$

which, when the dielectric constant ϵ is considered becomes the same value as that obtained from consideration of the double layer as a condenser, as under electrosmosis,

$e\delta = \zeta\epsilon/4\pi$, where ζ is the P. D. across the interface. This is the "same value which the moment of the double layer would form if the opposing electricities of the system were all concentrated into the interface. So it results that the entire cross section of the tube of liquid carries along an amount of electricity in unit time"

$$E_0 = \zeta\epsilon/4\pi \cdot \int \partial\mu/\partial\delta \cdot ds$$

which is proportional to the P. D. across the interface, the dielectric constant of the liquid, the average velocity of the flowing liquid $\partial\mu/\partial\delta$ and to the surface of the layer (ds).

Integrating the latter expression of the above equation

$$\int \partial\mu/\partial\delta \cdot ds = -PA/\eta L$$

that is, the average velocity times the surface area of the tube is proportional to the hydrostatic pressure (P) and the area of cross section (A) and inversely proportional to the viscosity of the liquid (η) and to the length of the tube (L). This expression is a form of Poiseuille's Law governing the flow of liquids through capillary tubes. (The negative sign serves to indicate that the direction of flow of quantity E_0 is opposite to that of E_1 given below.) Then

$$E_0 = -\frac{PA\zeta\epsilon}{4\pi\eta L}$$

which is the amount of electricity which is carried along the tube per unit of time, and which would accumulate at one end of the tube if it were not for an electrical conductance through liquid in the tube in the opposite direction.

An electromotive force H, is thus created between the ends of the tube and the amount of electricity (E) which is conducted back through each area of cross section (A) in unit time will be

$$E_1 = HA/\sigma L$$

where (σ) is the specific resistance of the liquid.

If there is no other means of conductance than that through the column of liquid, an equilibrium will be established when

$$E_0 + E_1 = 0$$

then

$$\frac{H}{\sigma} = \frac{\zeta P \epsilon}{4\pi\eta} \text{ or } H = \frac{\zeta P \epsilon}{4\pi\eta\kappa}$$

This equation shows that the E. M. F. (H) observed when a liquid is forced through a capillary across the ends of which there is a difference of

hydrostatic potential (P), is directly proportional to (P), to the potential difference across the interface solid-liquid (ζ), and to the dielectric constant (ϵ) of the liquid. (H) is inversely proportional to the viscosity (η) of the liquid and to its specific conductivity (κ), but is *independent* of the *dimensions of the tube or diaphragm*, so long as the diaphragm material has *no conductivity in itself*. This equation was modified by Lamb²⁸ to include a term defining the slippage of the liquid layer along the face of the solid. However, this slippage is so small as compared with the relative motion of the liquid over the film of liquid which is in contact with the solid, that it is negligible.

It will be noted that the electrosmosis formula for the volume (v) flowing in unit time when the current (i) is kept a constant, and the streaming potential formula given above are both independent of the dimensions of the diaphragm.

$$v = \frac{\zeta i \epsilon}{4\pi\eta\kappa} \quad (\text{electrosmosis equation})$$

$$H = \frac{\zeta P \epsilon}{4\pi\eta\kappa} \quad (\text{streaming potential equation})$$

If these equations are correctly derived and no term is omitted from one which is considered in the other, the relation

$$v/i = H/P \text{ should hold.}$$

Saxen²⁹ determined with the same apparatus the electrosmotically transferred volume (v) and also the potential (H) for the streaming current. He used a clay plate for the diaphragm and, as liquids, solutions of zinc, cadmium and copper sulfates with electrodes of the corresponding metals so as to eliminate polarization disturbances. The values which he obtained show a very close approximation to the identity of these ratios when the other variables are held constant. Values for the ζ -potential obtained by either the electrosmosis or streaming potential method then should be identical.

Krulyt² used the streaming potential method to study the comparative effects of electrolytes on the ζ -potential of a surface and on colloid stability. He used glass tubes of various lengths and areas of cross section, and streamed electrolytes of low concentration through them under measured hydrostatic pressure. He measured the E. M. F. set up across the ends of the tube by means of non-polarizable Ag-AgCl electrodes and a potentiometer, using a capillary electrometer as the null instrument. For a given sample of glass and a given liquid, he found the value H/P to be a constant, but to be different for different samples of glass. He points out that Grumbach³⁰ in some studies on the influence of non-electrolytes in a millimolar KCl solution upon the streaming potential, found that there was some change in the H/P value given, as the cell was allowed to set for a few days. Krulyt verified this observation, but found it so small as to be negligible for all practical purposes.

Older experiments cited by G. de Villemontée³¹ stated that with solutions of copper, zinc and nickel sulfates, there was no streaming potential set up. The solutions used in these experiments contained 10 grams of salt per liter, however, and their conductivities were too high to allow any observable E. M. F. to be set up. There has been a good deal of data³²⁻³⁵ obtained by electrosmosis experiments which show that electrolytes, in general, decrease the ζ -potential on colloids, a fact that is of significance when we remember that electrolytes, in general, also decrease the stability of colloidal solutions.

Kruyt found that in very small concentrations of electrolytes, of the order of 100 μ mols per liter, KCl, HCl, and BaCl₂ increased (ζ) on glass, but quickly thereafter decreased it steadily in concentrations of the order of 200-1500 μ mols per liter, though never discharging it entirely. AlCl₃, the only trivalent metal he used, showed no indication of an increase of ζ , but in very low concentrations (less than 1 μ mol per liter) totally reversed the charge and maintained it reversed though approaching the value of zero again in higher concentrations.

Freundlich and his coworkers^{3, 36} made use of the streaming potential methods for determination of the ζ -potential on glass capillaries in their researches on the relationship between the "electrokinetic potential" and the "thermodynamic potential" of interfaces.

Borelius³⁷ was first to compare potentials measured tangentially to those measured perpendicularly to an interface. For his transverse measurements he used a paraffin diaphragm and salt solutions, and for the tangential measurements he took the cataphoretic measurement of Powis (loc. cit.) on paraffin oils.

Freundlich and Ettisch³⁸ used glass tubes for the tangential measurements on the ζ -potential and the thin glass electrode of Haber and Klemensiewicz³⁸ for the measurements of the ϵ -potential, i.e., the transverse potential. They showed that the ζ -potential was never more than a fraction of the ϵ -potential and that it was governed very largely by electrolyte conditions in the solution. The ϵ -potential was found to be entirely independent of the electrolyte concentration in the external solution with the exception of the H⁺ and OH⁻ ions. The glass electrode acts, then, as a hydrogen electrode. In order to explain this discrepancy between the two values, Freundlich points out³⁹ that it is necessary to make two assumptions. They are, first, the existence of a *diffuse* double layer in at least one of the phases (as postulated by Gouy^{40, 41}) which

diminishes in intensity gradually in the direction away from the interface. The second is that a layer of the liquid is held tightly at the surface of the solid and that the motion tangent to the surface is between the movable liquid phase and this thin layer of liquid adhering to the wall. (ζ) then can be thought of as varying with the fraction of ϵ -potential which is actually moved; that is to say, perhaps only a small fraction of the total potential from a point inside the solid phase to a point inside the liquid phase (which is the ϵ -potential) will exist across the two layers of liquid, movable and non-movable, and this fraction is ζ . Also the sign of the potential across these two layers could be reversed by the action of electrolytes without appreciably changing the ϵ -potential. The ϵ -potential is to be thought of as a "thermodynamic"-potential and to be governed by the Nernst formula. The ζ -potential will tell nothing about the ϵ -potential; but the ζ -potential will be a closer function of adsorption and other colloid qualities of the system than will the ϵ -potential.

In Freundlich's investigation, the action of KCl, BaCl₂, La(NO₃)₃ and Th(NO₃)₄ upon the ζ -potential on his glass tubes was observed. KCl and BaCl₂ gave an increase in ζ in concentrations between 1 and 10 μ mols, and decreased it to nearly zero in 1000 μ molar solutions. The KCl curve on the graph lay well above the BaCl₂ curve. La(NO₃)₃ caused no increase in ζ , but a steady decrease to not quite zero in 1000 μ molar solution. Th(NO₃)₄ reversed the charge in a 1 μ molar solution and reached maximum reversal at 10 μ molar solution, then decreasing again to approximately zero in a 1000 μ molar solution. The change in the ϵ -potential for the same solutions was relatively small and steadily in one direction, all curves on the graph being virtually parallel.

Assumptions upon which the Electrosmosis and Streaming Potential Formulae are based

ϵ -The dielectric constant of the liquid in the region of an interface is assumed to be equal to that of the liquid in bulk. Recent measurements of the dielectric constant of water in presence of an electrical field show that ϵ for water can be lowered from a value of 80 to a value of 1 by placing the water in an electrical field of the order of 500,000 volts per centimeter.* Helmholtz and Quincke (loc. cit.) estimated the distance across an interface as of the order of 10^{-8} centimeter, that is, the thickness of one molecule. If the ζ -potential were then of an order of 0.2 volts, it is easily seen that the liquid in the interfacial layer is being acted upon by an extremely high electrical field and its dielectric constant might be greatly reduced. According to the theory of Gouy (loc. cit.) on the existence of a diffuse double layer, which postulates a much greater distance between the centers of electrical charge than that estimated by Helmholtz, it seems probable that the electrical field extant in interfacial regions may not be high enough to entirely

* Statement made by Debye in a lecture before the Minnesota Section of the American Chemical Society and Society of Sigma Xi, April, 1927.

eliminate (ϵ) from the equation. Probably the actual value for (ϵ) lies somewhere between 80 and 1, and it may vary with the conditions in the interface.

With dilute salt solutions, ϵ may not remain unchanged. Walden, Ulrich and Werner⁴² have offered evidence that the addition of a salt to a pure liquid first decreases ϵ and then, with increased concentration of salt, increases it to a value greater than that of the pure solvent. This is the regular thing with organic solvents, although with water they observed only the initial drop. Kruyt and van der Willigen⁴³ have drawn the conclusion that the so-called antagonism of ions probably depends upon the fact that one of the electrolytes shows a maximum in apparent ζ -potential with increasing concentration, which effect is probably due to its influence on the dielectric constant of the liquid. Univalent electrolytes usually show this maximum with increasing concentration, but its exact position is not predictable; polyvalent ions do not always show it.

It is possible that there may be other effects, also, on the liquid in the interface than those due to the electric field. For instance, the density of water at the interface may be different from water in bulk. Data obtained by Cude and Hulett,⁴⁴ Harkins and Ewing,⁴⁵ and Williams⁴⁶ show that there is a difference in the apparent density of charcoal in different liquids and they assume this to be due to differences in compressibilities of these liquids on the surface. Lamb and Coolidge⁴⁷ assumed the total heat of adsorption to be due to compression of liquid in the interface and calculated a pressure of 37,000 atmospheres as the compressing force exerted there. Rideal⁴⁸ refuses to believe that this effect will function to a greater distance from the surface of the solid than upon the monomolecular layer on that surface and explains the anomalous results obtained on charcoal densities as due to differences in the penetration (into the pores of the charcoal) or wetting properties of the various liquids.

η -The viscosity of the liquid is assumed to remain a constant for dilute salt solutions and to be equal to that of the pure liquid in the bulk. That the viscosity of the liquid in the interface does not vary from that value ordinarily given for the liquid is very probable, due to the fact that the viscosity measurements are themselves measurements of the resistance to shearing motion at an interface. However, it is possible that even in dilute solutions, (η) may be affected, due to adsorption of the electrolyte into the interface and a consequent increase in the effective concentration of the electrolyte in that part of the system. Helmholtz's and Perrin's equation leaves out of consideration, also, any effect due to slippage of the liquid layer

along the surface of the solid, assuming all motion to be between two liquid layers, where η would be the only factor. Lamb,²⁸ however, introduces a term, $1/\beta$, into all the equations of Helmholtz, where β = the coefficient of slippage at solid-liquid interface and l = linear magnitude of this slippage. This is not considered of importance in later treatments of the subject.

δ —The distance between the layers is not to be thought of as the actual distance between two plane surfaces as Helmholtz pictured it, but rather the distance between the electrical centers of gravity of two diffuse layers. Lippmann,⁴⁹ from considerations of the interfacial tension-voltage curve of mercury against sulfuric acid, as in a capillary electrometer, concluded (δ) was independent of the charge across the interface and of the sign of this charge. That this was an exceptional case was pointed out by Gouy⁴¹ who showed that δ was not constant and that the double layers were to be considered not as flat surfaces but as diffuse layers. This conception of the double layer finds its theoretical foundation in the kinetic theory of heat, which makes it very unlikely that all the ions would be distributed in a single plane in the liquid. (See also Billiter).⁵⁰ Rideal states, "At the beginning of the present century, when molecular magnitudes became more exactly known, it became apparent that δ was smaller than an atomic diameter. It was therefore suggested that the charges of the double layer must be regarded as separated by a dielectric medium. The thickness of the double layer is increased eighty fold if pure water be regarded as the intervening medium, but even if the dielectric constant of so thin a layer be considered less than that of water in bulk the thickness will still be of a possible order of magnitude. The variations in δ may thus be attributed to a variation either in the thickness of the double layer or in the effective dielectric constant, or to a combination of both."⁵¹

δ , the distance between the double layers, then, is variable, and may, in cases where polyvalent ions or other very capillary active ions are present in the solution, become so small as to exclude any great relative motions in the two layers, causing an anomalous lowering of ζ -potential.

In the derivation of the equations for the determination of ζ it will be remembered that (δ), the distance between the electrical double layers, was equated to (δ), the distance between the layer of no motion and the layer of maximum velocity. It is very unlikely that these distances will be identical or that they will vary in the same manner and degree with changes in the environment. It seems probable that herein lies the principal fallacy inherent in these equations. However, at present it cannot be eliminated.

κ —The specific conductivity factor found in the equation refers to that of the liquid. In the derivation of the streaming potential formula it will be remembered that the solid phase is assumed to have a negligible amount of

⁴⁹ Lippmann: Sitz. Akad. Wiss. Berlin, p. 947 (1881), (Cited by Rideal: "Surface Chemistry", p. 211).

⁵⁰ Billiter: Z. physik. Chem., 45, 307 (1903).

⁵¹ Rideal: "Surface Chemistry", 212 (1926).

conductivity. Also any "surface conductance" is disregarded. Smoluchowski⁵² has pointed out that "surface conductivity" might become an important factor in electrokinetic measurements when the conductivity of the liquid was very low. It would become negligible in salt solutions of concentrations high enough to give the liquid phase an appreciably high conductivity. Stock⁵³ noted that quartz powder in such liquids as nitrobenzene, aniline, etc., greatly increase the apparent conductivity of these liquids. McBain⁵⁴ mentions experiments by Darke on the conductivity of dilute KCl in a quartz capillary which showed conductivity over that of the solution in bulk. From these considerations, he stated that Darke was attempting to make absolute measurements of electrosmosis, none of which had previously existed so far as he (McBain) knew. Fairbrother and Mastin⁵⁵ performed experiments which indicated a small increase in the apparent conductivity of dilute aqueous electrolytes in a porous diaphragm over that in bulk. These authors offer a method for electrosmosis determinations of ζ , in which they eliminate this source of error by measuring the "cell constant" of the diaphragm employed, using N/10 KCl solution, in which they assume the "surface conductance" to be very small in comparison with the "bulk conductance." Stamm⁵⁶ found that water used in electrosmosis experiments on wood sections had a specific conductivity of 5.43×10^{-6} mho, while the specific conductivity of the average transverse section of the wood impregnated with this water was 8.27×10^{-6} mho. This indicated that the actual water in the wood had a specific conductivity of perhaps 2 or 3 times that in bulk.

In the derivation of the streaming potential formula the quantity of electricity which is conducted back through the liquid in the tube in unit time, is

$$E_L = \frac{HA}{\sigma L} = \frac{H\pi r^2 \kappa_L}{L}$$

This is true when the conductivity (κ_L) is uniform over the whole area (πr^2) of the cross section of the tube and equal to the conductivity of the liquid in bulk. When the conductivity is changed in the region of the interface, a new term must be introduced to take care of this variation.

Let (R) denote the radius of the column of liquid (in the tube) in which the conductivity is that of the liquid in bulk, and (δ) be the distance perpendicular to the wall in which the conductivity is changed, and in which the average conductivity is κ_s . The total radius of the tube then will be $R + \delta$. The amount of electricity (E_s) conducted through the volume adjacent to the wall (i.e., the surface conductance) equals

⁵² von Smoluchowski: *Physik. Z.*, **6**, 529 (1905); *Anz. Akad. Wiss. Krakov*, 1903 A, 185.

⁵³ Stock: *Anz. Akad. Wiss. Krakov*, 1912, A, 635. (Cited by Stamm: *Colloid Symposium Monograph*, Vol. IV, p. 246).

⁵⁴ McBain: *Trans. Faraday Soc.*, Joint Symposium of Faraday and Physics Societies, 1921, 150.

⁵⁵ Fairbrother and Mastin: *J. Chem. Soc.*, 125, 2319 (1924).

⁵⁶ Stamm: *Colloid Symposium Monograph*, 4, 246 (1926).

$$E_s = \frac{H(\pi R^2 - \pi R^2 + \pi R\delta + \pi\delta^2)}{L} \cdot \kappa_s$$

$$= \frac{H\pi}{L} (R\delta + \delta^2) \kappa_s$$

The amount of electricity carried by the bulk of liquid will be

$$E_L = \frac{H\pi R^2 \kappa_L}{L}$$

where κ_L = the specific conductivity of the liquid in bulk.

The total amount of electricity conducted then, is

$$E_T = E_L + E_s = (H\pi/L) [R^2 \kappa_L + (R\delta + \delta^2) \kappa_s]$$

When the specific conductivity of the liquid (κ_L) is employed, the equation given above for the streaming potential will hold only when there is no surface conductance; otherwise the dimensions of the tube must appear in the equation. That the surface conductance was negligible in the case of glass tube experiments with streaming potential as carried out by Krut and by Freundlich (loc. cit.) is evidenced by the constant value of H/P which they obtained with any given sample of glass regardless of the dimensions of the tube.

If we could consider the diffuse double layer of Gouy (loc. cit.) as extending to the center of the capillary, then the value of R in the equation given above would become equal to zero and

$$E_T = \frac{H\pi\delta^2 \kappa_s}{L}$$

would denote correctly the quantity of electricity flowing back through the tube in unit time. If we could then measure the average conductivity of the liquid (κ_s) in the tube or diaphragm, an absolute value of ζ would be obtainable by the streaming potential method. Gouy calculated the values of δ for a surface, the charge over unit area of which amounted to 10 electrostatic units, and obtained the following: (in these values, δ -stands for the electrical center of gravity of the diffuse layer)

	δ	
Solutions N/100 in ions	— 0.96 $\mu\mu$	
Solutions N/1000 in ions	— 9.6 $\mu\mu$	
Pure water (Kohlrausch)	— 1010 $\mu\mu$	

For low potentials and dilute solutions, then, δ may attain a considerable value (compared with molecular dimensions), even comparable to the radius of the tubes in a tightly packed diaphragm. Determination of the value (κ_s) may be made according to the method of Fairbrother and Mastin (loc. cit.) by measuring the "cell constant" for the diaphragm with N/10 KCl solution and calculating the specific conductivity of any other liquid which may be streamed through it. The surface conductance in the case of N/10

KCl solution would be very low, as they pointed out, in comparison to the bulk conductivity. Gouy's values for the thickness of the surface conducting layer (δ) in a N/10 solution also bear out this conclusion.

Another assumption which we must make when we use this equation for the streaming potential, is that the conditions of the capillaries of the diaphragm do not differ much from those postulated for the simple capillary pictured in the process of derivation of the equation. Poiseuille's Law holds for simple cylindrical capillaries of not too large diameter, and with pressures low enough not to cause turbulent flow. We must assume that it also holds for the average capillary of the diaphragm and must use pressures low enough so that turbulent flow is not produced.

That the ζ -potential appears to have a temperature coefficient is indicated by work of Cruse⁵⁷ who found that with a clay diaphragm and distilled water, a maximum was obtained for (ζ) at a temperature of 40°C. Smoluchowski⁵² claimed this change to be due to the fact that the factor $\eta\kappa/\epsilon$ did not remain a constant with change of temperature. Briggs, Bennett, and Pierson⁵⁸ say that their investigations show that the change in rate of volume flow in electrosmosis experiments is a function of the viscosity change with temperature, and that no maximum occurs. Cruse's results, they claim to be due to the failure of the diaphragm to come to equilibrium with the liquid before the readings were taken. (Gee and Harrison⁵⁹ measured the value of (κ) with change in temperature for the water they used, adopted values of (η) from Landolt-Börnstein and values of (ϵ) given by Drude, and obtained for temperatures ranging between 15°C. and 80°C., values for $\eta\kappa/\epsilon$ which were very close to a constant, thus indicating that the variation observed by Cruse was due to a variation in (ζ). It is of interest that Gee and Harrison should observe a like maximum of the ζ -potential on wool, cotton, and silk fibers at approximately the same temperature as that of Cruse on clay, i.e., 35°C.-40°C.

The ζ -potential on Cellulose

Scattered instances of ζ -potential measurements on cellulose have been made by means of the electrosmosis methods. Perrin^{13, 14} in his studies upon the influence of dissolved electrolytes on various colloids, found that in an electrosmosis apparatus in which the voltage drop was 10 volts per centimeter, a diaphragm of cotton fibers 1.4 centimeters in cross section gave the following values for the rate of flow in acid and alkali concentrations:

N/50	HCl	0 cc.	per minute
N/500	HCl	20 cc.	" "
N/500	KOH	70 cc.	" "

Larguier des Bancel's⁶⁰ showed that the negative charge on cellulose increased in alkali solutions and decreased in acid solutions, and, also, that polyvalent positive ions (Ca, Zn, Ba) decreased this charge while polyvalent negative ions (SO_4 and $\text{Fe}(\text{CN})_6$) increased it.

⁵⁷ Cruse: *Physik. Z.*, **6**, 201 (1905).

⁵⁸ Briggs, Bennett, and Pierson: *J. Phys. Chem.*, **22**, 256 (1918).

⁵⁹ Gee and Harrison: *Trans. Faraday Soc.*, **6**, 42 (1910).

⁶⁰ des Bancel's: *Compt. rend.*, **149**, 316 (1909).

German Patents⁶¹ note the migration of cellulose fibers toward the positive pole under stress of an electrical field, but no measurements of this effect are given.

In all instances, no attempt is made toward obtaining absolute values for the charge at the interface. They give only comparative values which show qualitatively the effects which electrolytes have on the charge, values which are not necessarily duplicable even when the same sample of cellulose is used again.

Gee and Harrison,⁵⁹ and Harrison,⁶² in developing their electrical theory of dyeing, used the streaming potential method for determining the ζ -potential on cotton, silk, and wool fibers against pure water and against solutions of various electrolytes and dyestuffs. A description of the apparatus used, is given in the second paper referred to. They found that: (a) acids increase the charge on a positively charged fiber and decrease it on a negatively charged fiber; (b) all acids act the same when the H ion concentration is the same; (c) bases act oppositely to acids; (d) when a salt is used as the electrolyte, ions of the opposite charge to that of the fiber have the most effect and the charge may be reversed by such ions; (e) polyvalent ions have greatest effects; and (f) the charge on a negative fiber (cotton, wool, silk) against water is greatest at the temperature of 40°C.

In their measurements they packed the fibers into a cell between two platinum electrodes and measured the electromotive force set up when the liquid was forced through this diaphragm. Due to a polarization of electrodes, they could not use an ordinary potentiometer, but had to measure the electromotive force in a manner which called for no flow of current through the electrodes. This they accomplished by charging a condenser from the streaming potential cell and then measuring the discharge of this condenser through a ballistic galvanometer. They measured the specific conductivity of the liquid by a conductivity cell arranged to utilize the liquid after it had passed through the diaphragm. These measurements are the most accurate made on cellulose and approach more nearly absolute measurements than those made by use of the electrophoresis method.

Development of Method

From a consideration of the results obtained by Kruyt² using capillary glass tubes and the streaming potential method for the determination of ζ , it was thought that similar results might be obtained by packing cellulose tightly into a compartment between two electrodes and forcing a liquid through it. Kruyt obtained constant values of H/P which were independent of the dimensions of the glass tube. The values for H/P, using cellulose as a diaphragm, should likewise be constant and independent of the tightness with which it might be packed.

⁶² Harrison: J. Soc. Dyers and Colourists, 27, 278 (1911).

Accordingly, an apparatus was prepared and such measurements were attempted. As a cell, the apparatus illustrated in Fig. 1 was used. This cell had previously been used in electrosmosis experiments, and was virtually a U-tube with a chamber (C) in the horizontal section which could be filled with fibers, these being retained at each end by a porous platinum disk (D and D'). The platinum electrodes (E and E') which were formerly connected with a source of potential could now be used to conduct off any potential which might be brought about due to the motion of the liquid through the diaphragm. The liquid was forced through the cell in a direction from A

FIG. 1

to A', the disk D' being clamped between the jaws of the two halves of the cell, and therefore, able to withstand considerable pressure without distortion.

It was with this cell that an attempt was made to use a Leeds and Northrup Potentiometer (Type K) to measure the potential set up across the diaphragm, but it was found that the polarization of the electrodes made accurate measurements impossible. Calomel half cells, which are nonpolarizing, were then connected to the cell through the tubes and stopcocks (T and T'), but the added resistance offered by the longer path through water made it impossible to get enough current through to cause deflection in the galvanometer. It was then that the quadrant electrometer was substituted as the voltage measuring apparatus, and polarization troubles were decreased to a minimum, the original platinum electrodes being used.

For all preliminary experiments, the liquid used was distilled water caught directly from the still and having a specific conductivity of the order of 3×10^{-6} mhos. For diaphragm material, a bleached sulfite pulp which had been electrodyalized free of ash (ash content of order of .02 per cent) was used. This pulp was kept wet in an airtight container until ready to be used.

Among the first experiments, it was found that the ratio H/P was not a constant with variation in P unless the diaphragm was packed tightly enough

so that the higher pressures could cause no appreciable decrease in the volume occupied by the pulp. The following tables show this effect. Table I (a) shows results with a diaphragm of pulp only fairly tightly packed, and Table I (b) and (c) for a tight and a very tight diaphragm, respectively.

TABLE I (a)

Streaming Potential to Pressure Ratio not a Constant
for Different Diaphragms of Cellulose

P (cm.Hg.)	H (mv)	H/P
51.6	130	2.52
37.9	107	2.82

D.	50.2	131	2.61	.595	220	572

H/P was not constant for various degrees of packing, it seemed evident that this must be due to one of the following causes. Either there was a change in the conductivity with change in tightness of packing, or else the rate of flow of the liquid through the pulp came in some way into the equation. Table II shows results of an experiment made to find whether or not rate of flow (R) played any part. These results are obtained with diaphragms of different tightness of packing, using a uniform pressure (P) on each.

In all experiments shown in Table II, the tightest packing of the pulp occurs as (A) and is progressively less tightly packed as we proceed down the table. In Table II (a) it appeared that the factor $H^2/P \times R$ was almost a constant, but the other experiments reversed this indication. Table III strengthens the conclusion that rate of flow does not play any determining part in the phenomenon. Table III shows a series of observations on the same diaphragm, at different pressures. The packing was tight enough to make H/P constant at these varying pressures.

TABLE III

Streaming Potentials not a Function of Rate of Flow for Given Diaphragm at Different Hydrostatic Pressures

Table III shows also, that rate of flow is proportional to pressure for a given diaphragm (there was a slight constant error made in this series of observation of pressure which became especially noticeable in low pressures).

These experiments indicated that (R) the rate of flow could not be utilized in obtaining a constant factor in streaming potential measurements. The other alternative, as mentioned above, was that the conductivity of the diaphragm was changing with tightness of packing. It was inconceivable that cellulose was acting as a conductor, and yet, when the amount of cellulose packed into a unit volume was increased, the H/P ratio decreased—a seeming indication that κ , the specific conductivity, was increasing. In Table II (b) a KCl solution was used. It was thought that the packing effect, if it was due to a difference in conductivity, would be very much reduced or disappear in a KCl solution, where the conductivity of the liquid was much higher than in the case of the distilled water. Table II (b), however, showed the packing effect as before. The work of Krulyt on glass tubes was repeated to see if, indeed, the value H/P was independent of the size of the capillary. Table IV shows the results of such an experiment, where tubes of the same glass but of four different sizes of cross section and length were used, and at various pressures. The rate of flow (R) is given to indicate the large difference in size of cross section of these tubes. The results of Krulyt are verified and the streaming potential thus shown to be independent of the size of the pores of the diaphragm.

TABLE IV
Streaming Potential to Pressure Ratio Constant for Glass Tubes
of Various Dimensions

Tube No.	P (cm.Hg.)	H (mv)	H/P	R (cc./sec.)
A	30.5	4370	143	1.56
	22.0	3100	141	1.21
	14.4	2140	147	0.89
B	15.5	2250	145	0.22

	19.40	2700	139	1.35
D	13.70	1990	145	0.16
	25.15	3605	143	0.30

The foregoing experiments having shown satisfactorily that the streaming potential was independent of rate of flow or of the dimensions of the pores of the diaphragm, it appeared, in spite of the results of Table II (b), with a KCl solution in place of water, that a change in conductivity was being brought about when more, or less, pulp was packed into the diaphragm chamber. Cellulose, being a non-conductor of electricity, should, if it had any influence at all on the conductivity through the diaphragm, decrease the conductivity because of the displacement of conducting liquid. However, the experimental evidence pointed toward the fact that when more cellulose

was added per unit of volume, the conductivity increased instead of decreasing, causing a lowering of the observed E. M. F. (H) instead of an increase, as might be expected. A simple experiment to find whether or not the presence of cellulose fibers in the water did increase its conductivity was made. A thin suspension of pulp in water was allowed to stand in a corked erlenmeyer for several hours to insure that an equilibrium was attained, should any salts be present in the pulp. Then a large conductivity cell was filled alternately with the water alone, and with the water containing pulp in suspension, and the specific conductivity taken. The results are as follows:

1. Light suspension of pulp—specific conductivity = 8.60×10^{-6} mhos
2. Water (nearly free from fibers) " " = 8.32×10^{-6} "
3. Somewhat heavier suspension of pulp—spec. cond. = 9.70×10^{-6} "
4. Water (entirely free of fibers)—" " = 8.20×10^{-6} "

These results removed any doubts as to the cause of the failure of H/P to remain constant. When such a great change in specific conductivity is indicated with such small amounts of fibers as could be sucked up into the conductivity cell, it can readily be understood that in the diaphragm, where the fibers are very tightly packed, the change in conductivity might be very large and readily account for the large discrepancy in the H/P values.

The new cell described under "Method" was now designed, the object being to measure the specific conductivity of the diaphragm (κ_b) upon which the streaming potential had been measured. Due to the fact that the area of cross section of the new cell was greater than that of the old cell, it was found necessary to pack the pulp more tightly into it in order to prevent H/P from varying with P. The values of H/P obtained with the new cell are therefore, correspondingly lower than those obtained with the old cell. It was thought that the factor $H\kappa_b/P$ would be a constant for different degrees of packing, where (κ_b) is the specific conductivity of the diaphragm as a whole. This value could be calculated from the value of the conductivity cell constant of the chamber (C) (Fig. 3), when a N/100 KCl solution was used to calibrate it, and the resistance across the diaphragm itself. We assumed that when the diaphragm material was packed into the compartment, the cell constant varied but little from the value obtained with N/100 KCl solution. The electrodes, which served as retainers for the cell contents were of gold heavy enough to withstand a good deal of pressure so that the dimensions of the cell would not change with the tightness of packing the pulp in it.

The results shown in Table V (a) seem to indicate that the value $H\kappa_b/P$ is a fair approximation to a constant for a sulfite pulp. The packing is progressively tighter from A to D; all cases are, however, packed with sufficient tightness so that H/P is a constant, with variation in pressure, for a given diaphragm.

This experiment was repeated with some quantitative filter paper (Schleicher and Schüll, No. 589). Table V (b) shows the results. The value $H\kappa_b/P$ is approximately constant for the different packings, but is different from that obtained for the electrolyzed sulfite pulp. Since this value

must be multiplied by a constant (1.0596×10^2) to obtain the ζ -potential, it appeared that ζ varied with the kind or history of the cellulose.

TABLE V

A More Constant Value for the ζ -Potential obtained when Specific Conductivity of Diaphragm (κ_D) is used in Place of Specific Conductivity of Liquid in Bulk in the Streaming Potential Formula

(a) For a Sample of Sulfite Pulp					
	P	H	H/P	$\kappa_D \cdot 10^4$	$\frac{H\kappa_D \cdot 10^4}{P}$
	(cm.Hg.)	(mv)		(mho)

	27.7	21.0	.76	2.90	2.20

(b) For a Sample of S. and S. Filter Paper					
	P	H	H/P	$\kappa_D \cdot 10^4$	$\frac{H\kappa_D \cdot 10^4}{P}$
	(cm.Hg.)	(mv)		(mho)	
A	31.6	345	10.9	6.0	6.52
	22.96	253	11.0	5.8	6.46
	12.7	143	11.1	5.7	6.30
	18.4	200	10.9	5.8	6.36
B	14.9	159	10.7	6.3	6.7
	20.2	213	10.6	6.3	6.7
	27.3	281	10.3	6.3	6.5

These results indicated a sufficient constancy in the value $H\kappa_D/P$ to warrant its use in comparing celluloses from various sources in order to find to what extent they might vary. Measurements were, therefore, made upon several dialyzed pulps and upon cotton, with the result that the values of $H\kappa_D/P$ all lay between the values given by the sulfite pulp shown in Table V (a) and the S. and S. filter paper of Table V (b). However, results on these samples of pulp seemed to cast doubt upon the constancy of this value for any given pulp when the tightness of packing was varied. Table VI shows this for a dialyzed short fiber pulp.

TABLE VI

Evidence that Specific Conductivity of Diaphragm is not the Correct Value to use in the Streaming Potential Formula for Calculation of ζ -Potential

P	H	H/P	$\kappa_D \cdot 10^5$	$\frac{H\kappa_D \cdot 10^5}{P}$
(cm.Hg.)	(mv)		(mho)	
28.0	100.0	3.66	1.80	6.5
17.0	69.0	4.05	1.60	6.5
14.8	53.6	3.62	1.56	5.6
10.0	36.7	3.67	1.50	5.9
Tighter pack—				
16.1	36	2.24	1.76	3.96
29.1	65	2.23	1.74	3.89

This difference might be explained by the fact that this sample of pulp still contained some soluble ions, and these were leaching out into the solution. In this case, the concentration of electrolyte would be lower in the less tightly packed diaphragm than in the more tightly packed diaphragm, due to a faster rate of flow. Then, if the ζ -potential were an inverse function of this ion concentration, it might be expected that it would be higher where the ion concentration was low. But while this is a possible explanation, further study of the derivation of the streaming potential formula showed that a discrepancy might be expected when the specific conductivity of the diaphragm (κ_D) was used in the equation in place of the specific conductivity of the liquid (κ_s) as it exists in the diaphragm. The specific conductivity of the diaphragm (κ_D) would give a value for ζ , which would more closely approximate the true value than if the specific conductivity of the liquid in bulk (κ_L) were used, as it could be when glass tubes were employed as the diaphragm. But the real value which should be used for the specific conductivity is that of the liquid (κ_s) as it exists in the diaphragm.

The increase in specific conductivity of the liquid when the fibers are placed in the cell is due to a "surface conductance" along the surface of the fibers. By measuring the "cell constant" of the diaphragm after the streaming potential measurements have been made, and from measurements of the resistance across the diaphragm simultaneously with the streaming potential measurements, it is possible to find this specific conductivity of the liquid (κ_s) in the pores.

The "cell constants" of the diaphragms used in calculating the specific conductivity of the liquid in the diaphragm (i.e. κ_s) were obtained by the use of N/10 KCl solution as the standard conducting liquid. It was assumed that at that concentration of electrolyte the surface conductance would be negligible. In order to determine to just what extent this assumption was correct, the following experiment was carried out.

If the surface conductivity with N/10 KCl was, indeed, negligible, a series of "cell constants" made on the diaphragm with solutions of KCl of lower normality should approach the "cell constant" obtained with N/10 KCl as a

limit, and the concentration, "cell constant" curve should show no indications of attaining a higher value with increase in concentration of the standardizing solution. A series of apparent "cell constants" were determined on diaphragms "B," in Table VIII (a), and "B" in Table VIII (b), using solutions of KCl ranging from N/1000 to N/10, the specific conductivities of which were measured at the same temperature as that of the diaphragm.* Table VII shows how the apparent "cell constant" varied due to surface conductance. The same values are shown graphically in Fig. 2.

FIG. 2

Showing the Apparent "Cell Constant" of Diaphragms of Two Samples of Cellulose—Determined with KCl Solutions of Various Normalities as Standard Conducting Solutions.

TABLE VII

Variation of "Cell Constant" of Diaphragm with Specific Conductivity of Standardizing Solution

KCl solution	"cell constants" —B (a)	—B (b)
N/10	.314	.353
N/50	.290	.314
N/100	.281	.284
N/200	.274	.245
N/500	.248	.179
N/1000	.226	.136

* All measurements were made in air at room temperature, 24°C, so that a small experimental error, due to temperature fluctuations of $\pm 1^\circ\text{C}$., will be present in all conductivity measurements made in this work. In most cases this error is of no great importance.

Attempts to obtain a mathematical expression for the curves given in Fig. 2 show that these curves are hyperbolas and may be expressed in equations of the form $-x/y = a + bx$. The following data indicate how closely an equation may be approximated. N = normality, C_o = "cell constant," C_c = "cell constant" calculated from the equation, and Δ the difference between C_o and C_c .

For curve (a) B—

N	C_o	N/C_o	C_c	Δ
0.100	0.314	0.31850	0.309	-0.005
0.020	0.290	0.06900	0.301	+0.011
0.010	0.281	0.03600	0.293	+0.012
0.005	0.274	0.01825	0.278	+0.004
0.002	0.248	0.00806	0.241	-0.007
0.001	0.226	0.00442	0.227	+0.001
				$\sigma\Delta \div 6 = 0.0066$

$$C_c = \frac{N}{0.00188 + 3.218 N}$$

From this equation C_c approaches the value 0.310 ± 0.0066 as a limit.

For curve (b) B—

N	C_o	N/C_o	C_c	Δ
0.100	0.353	0.2850	0.347	-0.004
0.020	0.314	0.0636	0.322	+0.008
0.010	0.284	0.0352	0.296	+0.012
0.005	0.245	0.0204	0.255	+0.010
0.002	0.179	0.0112	0.179	0.000
0.001	0.136	0.00735	0.120	-0.016
				$\Sigma\Delta \div 6 = 0.008$

$$C_c = \frac{N}{0.00551 + 2.825 N}$$

For this equation C_c approaches the value 0.355 ± 0.008 as a limit.

In the case of curve (a) B [Table VII] plotted from data obtained with S. and S. filter paper, the "cell constant" obtained with $N/10$ KCl may be taken as the true value, while with curve (b) B made with the sulfite pulp, the surface conductance of the pulp still plays a small rôle even in concentrations of that normality.

When the specific conductivity of the water in "bulk" (κ_L) was compared with the specific conductivity of this same water as it exists in the diaphragm (κ_s), it was found that in diaphragms of the sulfite pulp the conductivity of the water increased in the order of 35 to 65 times the bulk conductivity, while with the S. and S. filter paper pulp it was only 8 to 11 times as great, depending, of course, on the concentration of the pulp in the diaphragm.

The conclusion arrived at from this experiment is that the "cell constant" of a diaphragm, showing a high surface conductance effect, cannot be safely assumed to be that obtained with $N/10$ KCl as the standard solution and that a more concentrated electrolyte must be used in the determination; but

FIG. 3

with those diaphragms, having a relatively low surface conductance effect, the "cell constant" determined with N/10 KCl may be taken as the correct value.

Method

In Fig. 3 will be seen a diagram of the apparatus assemblage used for the determination of the ζ -potential on cellulose, or similar materials, by means of the streaming potential method. In order to calculate ζ from the equation

$\zeta = \frac{4\pi\eta\kappa H}{Pe}$, it is necessary to measure three variables simultaneously,

that is, (1) the hydrostatic pressure (P), (2) the electromotive force (H) set up across the diaphragm, and (3) the conductivity (κ) of the liquid within the diaphragm.

As a source of pressure, a tank (T) of about 50 liters capacity was used. Air was pumped into this tank until the desired pressure was attained. This air was passed through washing bottle (Bo) and into the reservoir (R) which contained the liquid which was being forced through the diaphragm. Pressure on the surface of the liquid in (R) was measured with the mercury manometer (M). To obtain the value for the pressure (P) on the diaphragm, the pressure, due to the water column between the surface of the liquid in (R) and the point of emission of the liquid from the cell, had to be subtracted from the manometer reading. Stopcocks, S_1 and S_2 , were used to release the pressure from the tank and the reservoir, respectively. Stopcock, S_3 , could be used to stop the flow of the liquid through the cell when desired. S_4 was needed to allow air to escape from the first chamber of the cell when this was being filled with liquid.

The cell which is used, is a combination conductivity cell and streaming potential cell. It consists of a glass center compartment (C) into which the diaphragm material is packed, two perforated gold electrodes (E), and two glass end compartments (G) with heavy glass flanges fitting up against the electrodes and which serve as supports for a clamp which holds the whole cell tightly together. In order to make the cell water tight, thin rubber washers cut from dental dam rubber are placed between the electrodes and the glass, care being taken that these do not cover any of the surface of the electrode which should be exposed to the contents of the chamber (C). The electrodes are disks made of 14 K gold, one millimeter thick and 45 millimeters in diameter. The portion of the electrode which is exposed to the center compartment (C) is perforated with one millimeter holes as thickly as possible without lowering its strength.

At a point on the circumference of each gold disk is soldered a platinum wire which will dip into mercury cups (MC) and from which contact will be made with the electrical measuring equipment. Facility with which measurements could be made was increased by the use of two six-point double-throw switches (W_1 and W_2). To insure perfect contact in the switches,

mercury cups and copper rockers were used. With switch (W_1) the cell could be connected either with the conductivity apparatus or the potentiometric apparatus.

Early in the research it was found that the ordinary potentiometer could not be used for measuring the streaming potentials in such a cell as described, because of polarization of the electrodes due to passage of current through them while the null point was being sought. Attempts were made to use liquid contacts and non-polarizing electrodes (calomel half-cells) with the potentiometer, but the added resistance to the circuit was so great as to prevent any deflection of the galvanometer or even of the capillary electrometer, which is much more sensitive than most galvanometers. It will be remembered that Harrison (*loc. cit.*) had similar trouble, and overcame it by using a condenser and ballistic galvanometer. In the present work, a quadrant electrometer (Q) was used. This instrument is a capacity potentiometer and requires an almost infinitesimal amount of electricity flowing from the electrodes to charge it. With it, the polarization trouble was always either reduced to a constant factor or totally eliminated.

Switch (W_2) is wired to connect the quadrant electrometer either to the streaming potential cell or to a Leeds and Northrup Portable Potentiometer (I) which served as a calibrating instrument. The deflection on scale (F) of the light reflected from the mirror attached to the needle of the quadrant electrometer could be calibrated with the L and N . Potentiometer and compared with readings taken from the streaming potential cell. The fiber used during the present measurements had a sensitivity of 125 mm. per 100 millivolts, at a scale distance of 1 meter. This made it possible to read potentials to an accuracy of approximately one millivolt.

The conductivity of the liquid in the diaphragm was measured with the aid of a ten meter bridge (B), ear phones (A), and high resistances (Re). The cell constant in the absence of diaphragm material was measured with $N/100$ KCl and found to be 0.146. The cell was reassembled several times and its conductivity constant remeasured. There was a very small variation in this value. This value of cell constant, however, is not of such great importance. As will be seen later, any variation in the cell due to difference in assembling is eliminated when the measurement of the "cell constant" of the diaphragm is made. The important point to be noted now is the fact that resistance measurements across the diaphragm may be made easily at any time. Most of the early measurements given in the present paper were made without actually determining the "cell constant" of the diaphragm. In these measurements the specific conductivity of the diaphragm (κ_p) as a whole was taken, and the value for the cell constant of the chamber (C), that is, 0.146, was used. The value $H\kappa_p/P$ appeared to be a fairly close approximation to a constant, at any rate, this factor is much nearer constant (for different tightnesses of packing) than the factor (H/P) which Krulyt and Freundlich (*loc. cit.*) found to be constant for glass tubes. However, it was later shown that there is a factor $H\kappa_s/P$ where (κ_s) is the specific conductivity of the liquid in the diaphragm determined in the following manner, which is more nearly a

constant value under very great difference in tightness of packing (and therefore, difference in dimensions of the capillaries in the diaphragm) than is $H\kappa_s/P$. In all future work the value (κ_s) will be used. When it is used the values for ζ become absolute, in so far as certain fundamental assumptions discussed above will allow.

The value (κ_s) is determined by measuring the resistance across the diaphragm while the liquid, against which the ζ -potential is desired, is in the diaphragm pores. Then after all streaming potential measurements are completed upon the sample, the "cell constant" of the diaphragm is obtained by replacing all liquid in the diaphragm with N/10 KCl (or a more concentrated soln., if needed), measuring the resistance across it and calculating the cell constant in the usual manner for any conductivity cell. Then from the measurements of resistance obtained while the experimental liquid was present, and the new "cell constant," the specific conductivity (κ_s) of this liquid may be calculated. Care must be taken to use a standard solution of KCl (or other electrolyte) which is of sufficient strength to eliminate all surface conductance effects from the diaphragm, when it is present, in order that the value of the "cell constant" may be correct.

From the values of (P), (H), and (κ_s) thus obtained, ζ may be calculated. The coefficient of viscosity (η) is taken as equal to 0.01. (ϵ), the dielectric constant of water, has been considered as having the value 80. (P), which is observed in centimeters of mercury, must be expressed in absolute units, that is, in dynes. This is obtained by multiplying the cm. Hg. observed by the specific gravity of mercury, 13.6, and the force of gravity in dynes acting on one gram, i.e., 981. (H), observed in millivolts, must be divided by 1000 to reduce it to volts and by 299.86 to reduce volts to c. g. s. electrostatic units. (1 c. g. s. electrostatic unit = 299.86 absolute volts.) (κ_s), observed in ohms⁻¹ must be multiplied by 9×10^{11} to convert it into c. g. s. electrostatic units. (1 c. g. s. electrostatic unit = 9×10^{11} absolute ohm-cms.) The value of ζ obtained would be in electrostatic units. In order to obtain this value in volts, it must be multiplied by 299.86.⁶³

Then

$$\begin{aligned}\zeta &= \frac{H\kappa_s}{P} \times \frac{9 \times 10^{11} \times 4 \times 3.1416 \times .01 \times 299.86}{13.6 \times 981 \times 10^3 \times 299.86 \times 80} \\ &= 1.0596 \times 10^2 \times \frac{H\kappa_s}{P}\end{aligned}$$

Where (ζ) is expressed in volts, (H) in millivolts, (κ_s) in reciprocal ohms and (P) in centimeters of mercury.

Results and Discussion

Results shown in Table VIII, (a), (b), and (c), serve to illustrate how constant the value $H\kappa_s/P$ has been found to be for three samples of paper pulp. Table VIII, (a) and (c), were obtained with samples of a quantitative filter paper (S. and S. No. 589). These two samples of filter paper were secured from the distributing firm at different times and were not of the same

⁶³ See International Critical Tables, 1, 27 (1926).

batch of paper. For Table VIII, (b), the diaphragms were made of the electrolyzed sulfite spruce pulp used throughout the development of the method. To insure uniformity of the pulp used in each series of diaphragms, these were prepared from a stock suspension of the pulp in water.

Fairbrother and Varley⁶⁴ have shown by electrosmosis experiments that sintered glass powder becomes hydrated on standing several days in contact with pure water and that the ζ -potential decreases as hydration increases, and it may become positively charged with solutions against which it formerly showed a negative charge. A similar phenomenon is noted with cellulose. If a dry sample of cellulose is allowed to stand a few days with water, a marked decrease in ζ -potential from the value given on the newly wetted pulp is observed. This decrease in ζ -potential approaches a limit with time and after a week the relative change per day is small. However, if the cellulose is placed in a ball-mill and beaten for a while, the ζ -potential again decreases and the decrease seems proportional to the degree of beating. Hydration seems therefore to decrease the ζ -potential on widely varied substances. The explanation probably lies in the variation in the fraction of the ϵ -potential which is extant between the fixed and movable layers of the liquid, the hydrated layer forcing the fixed-movable interface further into the liquid.

In Series (a) a comparison is made between $H \cdot \kappa_0/P$ and $H \cdot \kappa_s/P$. The "cell constants" of the diaphragms which were used in the calculation of κ_s were determined with $N/10$ KCl as the standard conductivity solution. The cell constant used in calculating κ_0 was that of the cell assembled with no pulp in it, which had the value, as mentioned before, of 0.146.

The dry weights of the diaphragms are given in Series (b) and (c) to indicate the relative tightness of pack of the diaphragms. The volume occupied being equal in every case, the tightness of pack is directly proportional to the weight of the diaphragm. In Series (c) the specific conductivity of the distilled water in bulk is given for each diaphragm. This value, (κ_L), when compared with (κ_s) shows that the specific conductivity of the water is increased from 9 to 10 times when it is in the diaphragm of S. and S. filter paper pulp. Though the bulk specific conductivity of the distilled water was not measured for Series (b) it may be considered of the same order of magnitude as that used in Series (c), in which case it will be seen that in contact with the sulfite pulp the specific conductivity of the water is increased 35 to 65 times, depending upon the size of the pores in the diaphragm. The "cell constants" used in calculating κ_s for diaphragms of Series (b) were measured with $N/5$ KCl instead of $N/10$, due to the fact that, in cases where the surface conductance is so high, this effect is still noticeable even when $N/10$ KCl is present as the liquid in the interstices of the diaphragm.

Values of the ζ -potential for the two samples of S. and S. filter paper (rag pulp) and for the sulfite pulp (wood pulp) are 0.0214 volts, 0.0161 volts, and 0.0083 volts, respectively. The ζ -potential on a sample of cellulose is a

⁶⁴ Fairbrother and Varley: J. Chem. Soc., 1927, 1584.

function of both its origin and history, the latter probably being the more important of the two.

These results indicate that, while the ζ -potential on cellulose is a variable from sample to sample, it can be determined accurately by the streaming potential method, provided a proper value for the conductivity (κ) in the streaming potential equation is obtained. This conclusion carries with it the corollary that the assumptions upon which the streaming potential equation is based are accurate and true within experimental error.

It is absolutely necessary in making ζ -potential measurements on cellulose and like colloids that foreign ions shall be absent. Traces of such ions, especially the polyvalent positive ions, will cause great variations in the ζ -potential. The accompanying Fig. 4 shows this effect with a series of chlorides of various positive ions (H, K, Mg, La, and Al) upon the value $H\kappa_b/P$ on diaphragms made from the S. and S. filter paper. These curves serve to illustrate one application of the method for measuring ζ given in this paper, that is, the study of ion effects upon colloids. These effects have

already been studied extensively by various methods, cataphoresis, electros-mosis, adsorption values, precipitation effects, etc. The advantage of the present method lies in its ease of manipulation and, we believe, the absolute character of the values obtained.

No discussion of Figure 4 will be given in the present paper, other than to point out some of the more interesting features. It will be seen that the Al^{+++} ion brings the cellulose to the iso-electric point at a concentration of about 0.0007 N, while none of the others, except possibly the H^+ , showed indications of reversing the charge. The K^+ ion, in very dilute solutions appears to increase the potential, while later decreasing it. As mentioned before, this effect may be due to a large change in the dielectric constant in low concentrations without a corresponding decrease in ζ to neutralize the effect. It is conceivable that at low concentrations, mixtures of K^+ and other ions (Mg^{++} , Al^{+++}) might be found where there was no apparent change in (ζ). This would be a case of ion antagonism. With the H^+ ion, the curve shows a

FIG. 4
Showing Ion Effects upon the ζ -Potential on Cellulose

decided tendency toward decreasing ζ up to a concentration of 0.0005 N, above which it was found impossible to make measurements, due to the enormous increase in surface conductance of the diaphragm when HCl was present. Al^{+++} and La^{+++} both definitely decreased the surface conductance of the pulp. This effect will also be studied more in detail later. The limiting factor in this method for studying ion effects is the conductivity. When this factor becomes too great, no measurements can be made. However, due to the fact that ion effects are usually those of extremely dilute solutions, this limitation is in most cases not of very great importance.

Summary

A method for the determination of ζ -potentials on colloid materials of such nature as cellulose, by means of the "streaming potential" measurements, is described.

A review of the literature and development of the "streaming potential" equation, together with the assumptions contained therein, is given.

Considerations are offered which indicate that measurements of the specific conductivity of the liquid in the diaphragm, which may vary widely from that of the liquid in bulk, may be made with a high degree of accuracy. The values for ζ resulting from the use of this value for the specific conductivity in the "streaming potential" equation, are to be regarded as absolute (not simply comparative) in so far as the assumptions relative to the other functions in the equation will allow.

Results indicate that ζ varies with the source and history of a sample of cellulose. An approximate value of ζ for two samples of a rag pulp and for a wood pulp are given; these values are .0214, .0161, and .0083 volts, respectively.

Acknowledgment

The writer takes this opportunity to express his deep appreciation for the advice and helpful suggestions given him during the prosecution of this research by Professors R. A. Gortner and J. J. Williams, of the Division of Agricultural Biochemistry, University of Minnesota. Their enthusiasm and personal interest in the problem have ever been a source of inspiration and of desire for attainment on the part of the writer.

In conclusion the author wishes to express his indebtedness to the Cloquet Wood Products companies of Cloquet, Minnesota, who provide the Cloquet Wood Products Fellowship at the University of Minnesota. This research fellowship was held by the author during the preliminary phases of the present research. Thanks are especially due to the Northwest Paper Company, of Cloquet, Minnesota, for materials and mill facilities.

A PHYSICO-CHEMICAL STUDY OF GUM ARABIC*

BY ARTHUR W. THOMAS AND HARRY A. MURRAY, JR.

There is very little in recent literature concerning the chemistry of gum arabic other than some isolated experimental facts. The complexity of the chemical behavior of the gums is frequently referred to their colloidal nature, and hence left for the present at least, as being not capable of explanation. This investigation was undertaken with the hope of establishing some definite stoichiometrical relations in connection with the colloid-chemical behavior of purified gum arabic.

Gum arabic occurs in the vegetable kingdom as the exudate of the *Acacia Senegal*. It is classified¹ as a colloidal polysaccharide. Such diverse colloids as dextrans, glycogen, cellulose, starch, mucilages, inulin and the true gums are in the same classification since they possess the common property of yielding upon hydrolysis, one or more sugars, generally pentoses or hexoses. Gum arabic is a typical true gum, i.e. it dissolves in water to form a clear filterable solution. Upon hydrolysis with sulphuric acid it yields the pentose sugar, arabinose, and relatively smaller quantities of the hexose sugar, galactose. The hydrolysis with sulphuric acid, also yields the so-called arabic acid nucleus to which the residues of arabinose and galactose are considered to be attached.² The "arabic acid" is of variable composition. The specific rotatory power varies from over plus 80 to minus 80 according to the origin. Herzfeld obtained from a levorotatory arabic acid 15.3 percent furfural and 11.5 percent mucic acid, and from a dextrorotatory arabic acid, 5.9 percent furfural and 41.7 percent mucic acid, showing the acid to be a galactoaraban of varying composition. Neubauer assigns the formula $(C_{12}H_{22}O_{11})_n$ to arabic acid,³ while O'Sullivan² gives it as $C_{88}H_{142}O_{74}$. Arabinose is the product of hydrolysis using both dilute and concentrated hydrochloric acid. The ash is reported to be about 3.5 percent, and is mainly calcium carbonate, with some potassium carbonate.²

A résumé, too extensive to include in this paper, of some qualitative tests for gum arabic and its quantitative determination are given in a Bureau of Standards Bulletin.⁵

The methods of purification may be roughly divided into two classes which in turn may be combined as was done in this investigation. The first depends upon the fact that gum arabic is insoluble in a solution containing more than 60 percent alcohol,⁶ and the second, that a membrane may be prepared to which the colloidal gum arabic is impermeable, and through which the mineral ions may pass. According to Graham, arabic acid containing but 0.1 percent of ash may be prepared in five days by dialyzing a 20 percent solution of the gum with 4 or 5 percent hydrochloric acid.⁷ O'Sullivan purified the gum by dissolving in water and adding two or three times as much hydrochloric acid

*Contribution from the Department of Chemistry, Columbia University, No. 560.

as was required to combine with the metals present. He repeated the procedure four times, washing free from chloride with alcohol. The specific rotatory powers of the four precipitates ranged from -25.7 to -27.0 indicating a homogeneous product.

Materials and Method of Purification

The material used in this investigation was "gum arabic" obtained from a jobber from stock shipped from Port Sudan, and is therefore the kind known as Sudan gum. It was purified as follows. A 100 gram portion of the commercial gum was dissolved in 500 cc of water, containing 5 cc of 12N hydrochloric acid. This solution was stirred mechanically for one half hour, after which alcohol was added slowly and with constant stirring to complete precipitation. In such a case the precipitate was fine, it settled and filtered readily. The precipitate was then filtered off through linen using suction. This operation, i.e., solution in water acidified with hydrochloric acid, and subsequent precipitation with alcohol, was repeated four times. The material thus obtained was dissolved in water and electrodialed for 50 hours. The solution was adjusted to $\text{pH} = 5.0$ by means of ammonium hydroxide and the electrodialysis continued until there was no test for the tenacious chloride ion in the diffusate. This required between 50-100 hours additional electrodialysis.

The electrodialysis was carried out in a three-compartment wooden cell,⁸ each compartment having a capacity of about 1500 cc. The membranes consisting of a coating of collodion on linen were fastened between the sections by means of bolts and rubber gaskets. The E. M. F. employed was 240 volts, and the only resistance used was that of the solution itself. Plates of carbon about 12×12 cm were used as electrodes. The carbon anode disintegrated badly and formed a carbon hydrosol in the compartment, but this introduced no complication since the carbon did not pass through the collodion membrane. The difficulty of testing for chloride ion in the anode compartment was overcome by the use of a platinum electrode at such times as the test was desirable. At no time was the temperature in the electrode compartments allowed to rise above 40°C .

There was a trace of reducing sugar in the original gum, one gram yielding 6 milligrams of cuprous oxide by the method of Quisumbing and Thomas,⁹ but immediately after purification the arabic acid did not reduce Fehling solution. At the end of four weeks, the stock arabic acid solution reduced Fehling solution slightly. The amount of reducing sugar present was a negligible factor for the following reasons. Its removal did not affect the specific rotatory power of the gum arabic, for that property was identical before and after purification. Further the optical rotatory power of the stock solution did not change even on long standing. The criteria of purity were the negligible amount of ash, and the uniformity of the product though the method of purification (time of dialysis) was varied, (50-100 hours). The purified product thus obtained will be referred to in this paper as arabic acid.

Four separate batches were prepared for use in this work, i.e. as one supply was being depleted, another was in the process of purification. The data obtained using all four solutions were concordant and reproducible though the supply of a given solution would last as long as five weeks during an investigation.

A one percent solution of purified arabic acid showed a pH value of 2.70 which is equivalent to that of a 0.02N solution of hydrochloric acid. This seemed unusual and was deemed worthy of investigation. Both the commercial gum arabic and the purified arabic acid were analyzed for phosphorus and sulphur in the thought that the presence of these substances as phosphates or sulphates, either naturally or by hydrolysis would account for the acidity. Sulphur was not present as shown by fusion with sodium and subsequent application of the sodium nitroprusside and methylene blue tests.¹⁰ The negative results were confirmed by fusion with sodium carbonate and potassium nitrate with subsequent test for barium sulphate.¹¹ Hence gum arabic is not a sulfuric acid ester as agar-agar has been shown to be.¹⁸

The phosphorus content was determined by fusion with sodium carbonate and potassium nitrate and subsequent treatment with ammonium phosphomolybdate solution.^{11, 12} There is a trace of phosphorus, not more than one tenth of one percent and not enough to account for the acidity. Further the nature of the titration curve, given later indicates that the acidity cannot be due to an acid as weak as phosphoric acid. Matthews¹ says that gums "nearly always contain phosphoric acid, which it is impossible to get entirely separated from the organic matter without hydrolysis. The phosphoric acid appears to be in union with the gum molecule and it is not impossible that it plays a very important part in the synthesis of the gum." It was felt that if the gum did yield the phosphate anion in solution it would have been removed during the purification process. If it were not, its presence in the amount indicated could not account for the acidity.

Apparently the high-molecular-weight arabic acid, the gummy residue so resistant to hydrolysis, is a strong acid.

In Table I is given a summary and a comparison of analyses made upon the commercial and purified products.

TABLE I
Summary of Analyses

	Commercial gum	Purified gum
$[\alpha]_D^{25^\circ}$ — (one percent solution)	-24.30	-24.30
Ash (percent)	2.78	0.08
Dextrin	none	none
Reducing sugar (mgm Cu ₂ O from 1 gr. gum)	6.5	none
Nitrogen (percent)	0.36	0.33
Phosphorus	trace (less than 0.1 percent)	trace (less than 0.1 percent)
Chloride ion	none	none
Sulphur	none	none

The purified arabic acid must be kept in solution, for the product on drying, either with alcohol or by heating (vacuum distillation) is rendered practically insoluble in water. The concentration of the stock solution was determined, and the samples used were taken from this stock solution.

* The original volume was that volume of stock solution which contained one gram of the arabic acid, usually from 15cc. to 20 cc.

portion of the purified arabic acid was titrated electrometrically* with 0.1N solutions of sodium hydroxide, barium hydroxide and hydrochloric acid. The data obtained are given in Table II and plotted in Fig. 1.

The curves for sodium and barium hydroxide are practically identical indicating that the arabic acid combines with alkali in equivalent proportions. The region of neutrality is between $\text{pH} = 5.0$ and $\text{pH} = 10.0$ and the end point (stoichiometric) indicates that 8.5cc of 0.1N alkali combine with one gram of acid. This result yields 1200 (1177) as the equivalent weight of the arabic acid. The sharp point of inflection on the curve bears out the conclusion that the acid is a strong one. The curve for hydrochloric acid suggests that the arabic acid is not amphoteric, a conclusion confirmed by further work reported later in this paper.

The Alkali-Binding Capacity of Arabic Acid

Introductory:—

The titration curves using sodium and barium hydroxides indicated that the arabic acid combined with bases according to the laws of primary valency, in brief as any simple inorganic acid and base combine. The next step taken to fix the simple stoichiometrical behavior of arabic acid was a measure of its base-combining capacity. No attempts were made here to determine an acid-combining capacity for preliminary studies in work to be described later clearly indicated that the arabic acid did not behave as a base. If it could be shown that one gram of arabic acid was capable of combining with a definite amount of alkali under different conditions, viz., varying concentrations of alkali, it was felt that our purpose to show the presence of true ionizable salts would be realized.

Procedure:—

The alkali-combining capacity was determined by a method similar to that described by Loeb¹⁴ and by Hoffman and Gortner.¹⁵

Varying normalities of sodium hydroxide were prepared in 25 cc volumetric flasks and the pH values determined potentiometrically. The data are given in Table III. The hydroxyl ion concentration was calculated from the observed pH using 1×10^{-14} as the dissociation constant for water. From these data a curve was plotted for subsequent calculations. This curve is not given here for economy of space.

A known weight of gum was placed in a 25 cc volumetric flask and the solution made up to a definite normality of sodium hydroxide by adding the same amount of standard alkali as before, that is when no acid is present. The pH value was determined, and the hydroxyl ion concentration calculated as above. By the ionization curve then, plotted from the data in Table III,

* The hydrogen ion concentrations of the equilibrium solutions in all the work in this paper were determined potentiometrically at room temperature. The hydrogen electrode used was the Hildebrand type as modified by Wilson.¹⁴ The calomel electrode used was of the type described by Wilson.¹⁵ Saturated potassium chloride (4.1N) was used and considered to eliminate liquid junction potentials. The potentiometer used was the portable hydrogen potentiometer (#7655) manufactured by the Leeds and Northrup Co., and said by them to have an accuracy of plus or minus 0.5 millivolts.

the equilibrium ion concentration obtaining in the sodium arabate solution can be changed into normality. The amount of base bound by the arabic acid in terms of normality was determined by the difference between the original normality (N) of the sodium hydroxide solution without the arabic acid, and the measured normality (N') of the sodium hydroxide solution containing the arabic acid, each having been made up to the same original normality. The amount of base bound by acid and designated by n is then equal to $N - N'$.

In this method of calculation it is necessary to assume that the same normality of alkali gives the same hydroxyl ion concentration whether arabate ion is present or not. The low concentration of arabate ion present would not in all probability materially affect the hydroxyl ion.

The data obtained on the solutions containing the arabic acid, and calculated as described above are given in Table IV.

Results:—

The errors involved in the calculation of base-combining capacity are large despite the fact that the potentiometric determinations are within the limit of experimental error. The potentiometer used is said by the manufacturers to be accurate to plus or minus 0.5 millivolts though it is not generally possible to remain in that range in the strongly alkaline solutions obtaining here.

If in the case of 0.05N sodium hydroxide one sample gave an E.M.F. of 980 millivolts and the other 980.5 millivolts the free sodium hydroxide would be 0.033 moles and 0.036 moles respectively. This would give 0.0170 moles and 0.0140 moles of base bound by a given weight of acid, i.e. an error of 20 percent. The values for moles of sodium hydroxide bound by one gram of gum given in the last column of Table IV differ by considerably more than 20 percent, but they are considered to be significant. They included a range of sodium hydroxide concentration from 0.01N to 0.24N and a range of arabic

acid concentration from 8.95 to 24.0 grams per liter. The average value from Table IV is 0.00106 moles per gram of gum from which an equivalent weight of about 1000 (943) for arabic acid is calculated. This value is in fairly good agreement with that obtained from the titration curve considering the errors involved.

The weight of evidence from the titration and alkali-combining capacity data is that a true salt, sodium arabate exists.

Osmotic Pressure as a Function of pH

Procedure:—

The method of R. S. Lillie described by Loeb¹⁴ was employed for the measurement of the osmotic pressure. Pyroxylin bags were made in a test tube of a size made by cutting in half an ordinary 6" by 1" test tube. The bags were prepared uniformly, that is by filling with collodion (Merck, 275 grains of ether per ounce, 27 percent alcohol, U.S.P. IX). The collodion was then poured slowly from the flask by rotating the latter. The process was timed to take 30 seconds. The flask with its adhering layer of collodion was then allowed to dry for fifteen minutes at room temperature, after which

FIG. 2

$\Delta - \Delta = \text{HCl}$. $\bullet - \bullet = \text{H}_3\text{PO}_4$. $\times = \text{H}_2\text{O}$. $\circ - \circ = \text{NaOH}$. $\square - \square = \text{Ba}(\text{OH})_2$.

Abscissae = pH.

Ordinates = Osmotic pressure in millimeters of solution.

water was allowed to run in slowly for five minutes. The bags were closed by tying with string to a one-hole rubber stopper. The bag was filled with the solution with the aid of a small funnel, all air bubbles were removed and a glass tube was pushed into the bag, through the stopper to serve as a manometer. The manometer and bag were inserted in a 400 cc wide-mouthed bottle containing 350 cc of solution by means of a two-holed rubber stopper. The solutions in the bottle and inside the manometer tubes were protected from the carbon dioxide of the air by means of soda-lime tubes. The surface of the stopper was so adjusted that it lay in the surface of the solution in the bottle. This apparatus was kept at 25°C by immersion in a water thermostat during the course of a measurement.

The water diffused from the outside bottle into the arabic acid solution, and the column of liquid in the manometer rose to a maximum usually reached in about 10 hours. Due to the fact that the pyroxylin bag is impermeable to the gum, a change in pH will occur due to the Donnan membrane equilibrium. It is true also that the solution inside the bag is diluted by the entrance of water into the collodion bag. Such a condition is met by filling the manometer tube to a point indicated as the osmotic equilibrium by preliminary experiments. It was not thought that such a procedure would be advantageous however, since it would undoubtedly retard uniform diffusion of the inside solution, and introduce as great an error as that caused by dilu-

tion. The heights* in the manometer tubes were recorded and the pH values of the solutions determined at the end of twenty-four hours.

Table V gives the data for the osmotic pressure and pH of solutions of originally one percent solutions of arabic acid, with two different bases, sodium hydroxide and barium hydroxide. This is shown graphically in Fig. 2.

The osmotic pressure is a maximum at a pH of 4.25, in the case of sodium arabate and 3.35 for barium arabate. The points for the two acids used lie on the same curve. The osmotic pressure of 248 mm. at pH = 3.05, is that of the pure gum solution in distilled water, to which neither acid nor base had been added. There is no evidence of an isoelectric point as is found in the case of proteins. At a pH of about 1.90 the curve is parallel to the abscissa; that is, the osmotic pressure has become constant and is due to molecules or particles of gum. Between the pH values of 5.0 and 10.0, the neutrality region, a flat portion of the curve is observed.

If the gum did not combine with the acid, according to the picture

we should find the concentration of hydrogen ion greater in the outside than in the inside solution because from the equation $x^2 = y(y + z)$, x must be greater than y . Such a condition was never found. Below a pH of 1.90 the hydrogen ion concentrations of the inside and outside solutions are identical, indicating that the gum did not combine with the acid.

The nature of the curves suggested that the membrane theory of Donnan might be applied, since both show a maximum osmotic pressure at a definite pH and fall away on both sides of the maximum point while the curve for the barium arabate falls below that of the sodium arabate.

One may examine qualitatively the effects of adding acid or alkali to the system by means of the osmotic pressure equation,—

$$\text{o.p.} = (2y + z - 2x)RT \quad (\text{I})$$

Picture the system as follows:—

* The difference in elasticity of the pyroxylin bags, subjected to varying pressures at the several heights also introduces an error, but the smoothness of the curve plotted, where the heights in millimeters are used, indicates that the error is not great.

From the Donnan theory then $x^2 = y(y + z)$ or $x = \sqrt{y(y + z)}$. Substituting this value of x in equation (I) above

$$\text{o.p.} = (2y + z - 2\sqrt{y(y + z)})RT$$

At a pH of 2.0, Fig. 3 and Table VI, x and y are equal, hence z must be zero since $z = \frac{(x + y)(x - y)}{y}$, and the observed osmotic pressure of 14

millimeters of solution is due to a . As y increases, z increases due to the formation of ionized arabic acid, or sodium arabate. At first z increases more rapidly than y , or until z has reached its limiting value fixed by the original concentration of arabic acid. From equation (I) the osmotic pressure must be a maximum at this point, and with increasing y , z becomes negligible in comparison to y , and the osmotic pressure diminishes approaching zero as its limit. It would be valuable to determine whether or not a point might be reached where x and y would again be equal, but the determination was not realized experimentally. The collodion bags dissolved in solutions more strongly alkaline than those used. The validity of the Donnan theory is apparently borne out further by the fact that at the same pH (4.25) the point on the barium arabate curve is about one half as high as that on the sodium arabate curve, which is what the theory demands, viz. for a monovalent cation equation (I) expresses the osmotic pressure, while for a divalent cation the

$$\text{o.p.} = 3/2y + z/2 - 3/2x.$$

There is no reason for thinking that the barium arabate is but half as highly ionized as sodium arabate.

A few experiments were conducted to show the effect of varying concentrations of a neutral salt, (sodium chloride) on the osmotic pressure of the arabic acid solutions. The results indicated that the osmotic pressure was depressed by the presence of neutral salt as was expected from a consideration of the Donnan theory.

Using the data in Table V, an attempt was made to calculate the osmotic pressure based on the following considerations. The inside solution was separated from the outside solution by a membrane impermeable to one of the ions, namely arabate ion, existing in the solution, thus giving rise, at equilibrium to an unequal distribution of ions across the membrane. The observed osmotic pressure was then the difference between the osmotic pressure of the inside solution, and the counter osmotic pressure of the outside solution.

The equilibria obtaining in the several cases are represented as follows.

Where both the inside and outside solutions are acid in the presence of sodium hydroxide (or barium dioxide) the picture is

Where both the inside and outside solutions are acid in the presence of hydrochloric acid, the picture is

In the special case of a one per cent solution of arabic acid, where both the inside and outside solutions are acid, the picture is

Where the inside solution is acid and the outside solution is alkaline, the picture is

Where both the inside and outside solutions are alkaline, the picture is

A typical calculation using data in the first horizontal row of Table V is as follows. In this case both the inside and outside solutions are acid in the presence of sodium hydroxide.

Inside	Outside
$C_{Na^+} = 52 \times 10^{-5}$ m.p.l. from Fig. 1	$C_{Na^+} = C_{OH^-} = 5.25 \times 10^{-9}$
$C_{H^+} = 42.7 \times 10^{-5}$ m.p.l.	$C_{H^+} = 0.19 \times 10^{-5}$
$C_{HAr} = 89.0 \times 10^{-5} - 42.7 \times 10^{-5} =$	$C_{CO_3^{--}} = 0.10 \times 10^{-5}$
46.3×10^{-5} m.p.l.	
Total ion conc. inside =	Total ion conc. outside —
141×10^{-5} m.p.l.	0.29×10^{-5} m.p.l.

Hence the osmotic pressure of the system is due to a concentration of ions equal to $141 \times 10^{-5} - 0.29 \times 10^{-5} = 140.71 \times 10^{-5}$ m.p.l. If the theoretical osmotic pressure of a gram molecular solution is expressed in terms of a column of water we get, at 25° C,

$$22.4 \times 760 \times 13.6 \times 298/273 = 2.5 \times 10^5 \text{ m.m.}$$

or in other words a theoretical pressure of 2.5 m.m. corresponds to a concentration of 10^{-5} normal. The calculated osmotic pressure is then

$$[140.71 \times 10^{-5}] [2.5 \times 10^5] = 352 \text{ m.m.}$$

whereas the observed value was 331 m.m.

Typical results of the calculations based on the data in Table V and the foregoing pictures of the equilibria are given in Table VI.

* The concentration of $HAr = H^+ + Ar^- = 89.0 \times 10^{-5}$ m.p.l. calculated from potentiometric measurement of 1% solution. Table VI.

As seen in Table VI, in the case of the 1% solution of arabic acid in distilled water, the calculated value for the osmotic pressure agrees closely with the observed value. This agreement is good likewise in the systems (1) where in the presence of sodium hydroxide (or barium hydroxide) both inside and outside solutions are acid, and (2) where in the presence of sodium hydroxide (or barium hydroxide), the inside solution is acid and the outside solution is slightly alkaline.

With increasing alkalinity in the outside solution, the divergence increases; and when both the inside and outside solutions become alkaline, the differences between the calculated and observed values are very large.

These marked differences may be due to a partial hydrolysis of the arabate ion in the strong alkaline solutions, or to a reaction between the alkali and the pyroxylin membranes, or both. It has been stated previously that the membranes disintegrated in the strongly alkaline solutions, and even in those cases, where results were reported, the bags became tender in twenty-four hours.

Where both the inside and outside solutions were acid in the presence of hydrochloric acid, the calculated values do not agree with the observed values. This lack of agreement is due probably to the fact that neither solution was analyzed for chloride and hence there is no measure of the equilibrium $\text{HAR} \rightleftharpoons \text{H}^+ + \text{Ar}^-$ which in distilled water indicates a concentration of 89.0×10^{-5} m.p.l. or a calculated osmotic pressure of 221 m.m. and in strong hydrochloric acid, where the pH values of both inside and outside solutions are identical, a calculated concentration of 5.6×10^{-5} m.p.l. from the observed osmotic pressure of 14 m.m.

The close agreement of the calculated and observed values in the cases not complicated by strong alkali indicates the validity of the pictures presented to show the equilibria. That is, there is an unequal distribution of ions across the semipermeable membrane and the arabate ion combines quantitatively with both sodium and barium ions.

Viscosity as a Function of pH

Introductory:—

In his work on the proteins, Loeb pointed out the very similar nature of the curves obtained when several of their properties such as osmotic pressure, membrane potentials, swelling and viscosity were considered as a function of pH. That is, in almost every case, starting with the isoelectric protein he was able to show a rise to a maximum on both sides of the isoelectric point when the property was plotted as a function of pH, and a subsequent decrease in the value of the property with increasing acidity or alkalinity. The curves obtained in the osmotic pressure study of alkaline arabate solutions, (Fig. 2) are similar in nature to those obtained by Loeb with proteins, in so far as the colloidal molecule functions as an anion. Viscosity of arabate solutions as a function of pH is not unlike the osmotic pressure pH curve. In neither case was evidence for an arabic cation found.

The viscosity of a solution has been definitely shown to be a function of the volume of the solute in the solution,¹⁴ or what is the same thing, a function of the free volume of the solute.¹¹ The free volume is the difference between the volume occupied by the molecules, and that volume filled by the molecules on the assumption of tetrahedral close packing.

The increase and decrease in viscosity of the gum arabic acid solution must depend then upon some mechanism whereby the molecules may increase and decrease their volume.

When gum arabic is dissolved in water, it swells to some extent before going into solution. Further it is well known that gum arabic may be ren-

FIG. 3

Viscosity as a function of pH and of neutral salt concentration. ● — ● = Effect of sodium chloride. ○ — ○ = effect of pH.

Bottom abscissae = Concentration of salt.

Ordinates = Viscosity ratio (water = 100).

dered insoluble by extreme drying either with alcohol or by heating. When it is thus dried, the gum swells in water to a jelly-like mass which does not dissolve except on long standing. We have here evidence of swelling, hence a mechanism by which the gum arabic acid may increase or decrease its relative volume in the solution.

According to Procter and Wilson the force which causes swelling is an osmotic force, i.e. the diffusion of water through a membrane. In this case the membrane is the arabate ions or aggregates, and the forces which limit the swelling are the cohesive forces obtaining between the arabate ions.

Procedure:—

The time of the outflow of the gum arabic acid solution through an Ostwald viscometer, was measured at 25°C. The quotient of this time divided by the time of outflow of water through the same tube and at the same temperature is referred to as the viscosity ratio of the gum arabic acid solution. The viscosity ratio was determined for one percent gum arabic acid solutions over a range of pH from 0.74 to 13.33 obtained by using hydrochloric acid, and sodium hydroxide. A series was not run using a divalent cation, Ba⁺⁺, because of the experimental difficulties involved in the handling of the barium arabate solutions, containing an excess of barium hydroxide.

In Table VII are given data obtained by measuring the time of outflow immediately after the solutions were prepared. In Table VIII are given data obtained by measuring the time of outflow 15 hours after the solutions were prepared. Inasmuch as the purified stock of gum arabic acid must be kept in solution, the possibility of learning whether swelling, hence viscosity increases on standing was precluded. Since the data for both series lie on the same curve, Fig. 3, the results do confirm the resistance of the gum arabic

acid to hydrolysis. In connection with this work the specific rotatory power was measured at the different pH values, and was found not to be dependent upon them. The specific rotatory power is indeed identical with that of the purified gum arabic acid stock solution in every case.

TABLE VIII
Viscosity as a function of pH (15 hours)

Acid or alkali	E.M.F.	pH	Viscosity ratio	Acid or alkali	E.M.F.	pH	Viscosity ratio
HCl	0.3026	0.96	1.19	NaOH	0.8595	10.38	2.14
	0.3290	1.41	1.18		0.9008	11.09	1.91
	0.3816	2.28	1.21		0.9206	11.38	1.64
					0.9616	12.12	1.33
H ₂ O	0.4072	2.71	1.49		1.0018	12.79	1.25
					1.0316	13.30	1.22
NaOH	0.5186	4.60	2.50		1.0484	13.51	1.29
	0.5219	4.66	2.51				
	0.6950	7.60	2.54				
	0.8534	10.26	2.47				

Results:—

The data lie on a smooth curve the maximum point of which is a viscosity ratio of 2.54 at pH = 4.58 to 6.30. In the region between pH = 5 and 10 this curve, as well as those of the titration and osmotic pressure—pH curves, indicates a gradual change in property with marked change in pH.

Since the Donnan theory was applied qualitatively in the case of osmotic pressure it was attempted to make the same application here. The theory demands the presence of a membrane impermeable to at least one ion, a condition satisfied in the osmotic pressure work by the collodion membrane impermeable to the arabate ion. In the case of viscosity the arabate particles themselves act as the membrane. They are held together as suggested by cohesive forces. They cannot diffuse then, and hence effect no appreciable osmotic pressure. The Na⁺ or H⁺ ions held to them by electrostatic attraction can diffuse and hence exercise osmotic pressure. Conditions are right then for the establishment of the Donnan membrane equilibrium. Let e represent the osmotic force which causes swelling. Then

$$e = 2y + z^2 - x$$

an equation identical with that for osmotic pressure discussed in the previous section.

Now from the Donnan equation

$$y = \frac{-z + \sqrt{z^2 + 4x^2}}{2}$$

Substituting this value of y in the above equation we have

$$e = -2x + \sqrt{(4x^2 + z^2)} \quad (II)$$

We may picture the system exactly as was done under the discussion osmotic pressure.

Starting at a pH of 2.0, Fig. 2, as before, as x increases, that is decreasing concentration of hydrogen ion, z also increases and at a faster rate than x , until its limiting value is reached. The value of z is limited by the concentration of gum arabic acid in the solution. If the ionization of gum arabic acid or of sodium arabate were sufficiently repressed by increasing x (addition of sodium hydroxide) then z would diminish. In any case, taking the last term of equation (II) above

$$\lim_{x = \infty} \sqrt{4x^2 + z^2} = \sqrt{4x^2}$$

from which

$$\lim_{x = \infty} e = 0$$

showing that as x increases, e increases to a maximum and then decreases. The conclusion would be true whether or not the ionization of the sodium arabate was extensively repressed.

The data and curve show very definitely the increase of the viscosity ratio from a minimum to a maximum with a subsequent decrease. This behavior, the change of viscosity with hydrogen ion concentration, is thus qualitatively in accordance with the Donnan membrane equilibrium.

The Effect of Neutral Salts on Viscosity

The properties, osmotic pressure and viscosity, of arabic acid solutions have been shown to be a function of the hydrogen ion concentrations of the solutions, and further the behavior has qualitatively followed the Donnan theory. So far the behavior of the carbohydrate, arabic acid, has been shown to be very like that of proteins in respect to the conditions and explanations mentioned.

Several observers, Hofmeister, Pauli, Sackur, Lillie, and Loeb, have remarked that neutral salts depressed these properties of proteins, and it was shown by Loeb that when the measurements were made at the same hydrogen ion concentration, the results were explained by the Donnan theory.

Procedure:—

To 0.25 gram of gum arabic acid in a 25 cc volumetric flask, sufficient 0.1N sodium hydroxide was added to bring it to a pH of 7.85. Varying amounts of a sodium chloride solution previously brought to a pH of 7.85 by sodium hydroxide were then added to the flasks. The solutions in the flasks were brought to volume by the addition of water having a pH of 7.85, obtained by using sodium hydroxide. In such a manner one percent solutions of arabic acid, containing varying concentrations of sodium chloride and having the same pH value were obtained.

The viscosity ratios of the solutions were then measured in the manner hitherto described. The data are given in Table IX, and are plotted in Fig. 3.

Results:—

The curve shows that the viscosity is depressed by neutral salts, the more, the greater the concentration of the salt. This behavior may be explained on the basis of the Donnan theory using the picture just given. That is, in the case at hand, when sodium chloride is added to a sodium arabate solution both x and y are increased, that is, the Na^+ in the outside solution and the Na^+ ions which are not in combination with the arabate ions, in the inside solution. The concentration, z , of Na^+ in combination with the arabate ions remains the same at the same pH (neglecting repression of ionization of sodium arabate). Further x , is greater than y always. As x increases, approaching infinity as a limit, the viscosity decreases continuously to zero.

Again the experimental facts confirm what might have been predicted from a qualitative consideration of the Donnan theory. The marked change in viscosity with change in pH value, as well as the depression of the viscosity by sodium chloride, indicates that gum arabic exists in the form of micells like gelatin.

TABLE IX

*pH = 7.85.

Summary

A study of certain phases of the physico-chemical behavior of the colloidal polysaccharide, gum arabic, is offered. In the report a method of purification has been described and certain properties investigated.

The equivalent weight of the acid was found to be about 1200 from its base-combining capacity measured by titration with sodium and barium hydroxides, and about 1000 when varying concentrations of alkali and arabic acid were used in measuring the base-combining capacity.

The nature of the titration curve and the agreement of the equivalent weight of arabic acid calculated from it, with that value obtained from a measurement of the base-combining capacity, indicate that the reaction between arabic acid and alkalis is a simple chemical combination involving primary valence forces.

The calculated values of the osmotic pressure based on potentiometric measurements are in fair agreement with the observed values within the limits of accuracy of the technique and provided the solutions are not too alkaline. The qualitative application of the Donnan theory to the results obtained when osmotic pressure and viscosity were measured as a function of hydrogen ion and neutral salt concentrations was successful, and accounted for the nature of the curves, in short its colloidal behavior.

THE PREPARATION OF A LEAD SELENIDE HYDROSOL

BY J. BROOKS

The present paper describes the preparation of a colloidal solution of lead selenide. As some of the factors involved are not without interest for colloid formation in general the method is described in detail.

It was desired that the sol should possess the following properties:—

- (a) that it should contain a fairly high concentration of colloid (up to 0.5 per cent lead as lead selenide.)
- (b) that it should be free from any but negligible amounts of ionic lead.
- (c) that it should be stable on boiling in the presence of 1.0 per cent sodium chloride.

The usual methods for the preparation of colloidal metallic sulphides were first used, employing hydrogen selenide in place of hydrogen sulphide; these were:

- (A) the action of H_2Se on aqueous solutions of lead salts.
- (B) the action of H_2Se on freshly precipitated lead hydroxide or lead selenide suspended in water.

As the dilute sols thus obtained were flocculated by NaCl , gelatin was used as a protective agent and the same experiments were repeated in the presence of 0.5 per cent of this substance.

The action of H_2Se on PbSe suspended in the gelatin solution gave a sol containing only 0.06 per cent Pb (as PbSe). With suspended lead hydroxide more concentrated sols were obtained, but the conversion of hydroxide into selenide was slow. Ultra-filtration showed that both sols contained negligible amounts of ionic lead. The passage of H_2Se into a solution of lead acetate and gelatin gave stable sols but ultra-filtration showed that they contained ionic lead in concentrations which increased with the initial concentration of lead acetate used. This was apparently due to the presence of the acetic acid formed.¹

Sufficient sodium bicarbonate to neutralise the acetic acid produced was therefore added before the removal of excess H_2Se .

Experimental

The method used was as follows. Air was first removed² from a boiling solution of lead acetate containing 0.5 per cent gelatin by the passage of nitrogen through the apparatus. After cooling the solution to room tempera-

¹ Before ultra-filtration the excess H_2Se present at the end of the reaction was removed by bubbling with nitrogen. In the presence of acetic acid continued removal of H_2Se would lead to a reversal of the above reaction with a consequent increase of the amount of Pb^{++} present.

² This is rendered necessary by the rapid oxidation of hydrogen selenide to selenium by atmospheric oxygen.

ture H_2Se (generated by the action of H_2O on phosphorus selenide at 100°) was led into the stirred solution (300-400 revolutions per minute). After the passage of excess H_2Se the calculated amount of $\text{N}/2 \text{ NaHCO}_3$ was added to neutralise the acetic acid present. The excess of toxic gas was then removed by raising the sol to boiling point during the passage of a further stream of nitrogen. Coarse particles of PbSe were removed by centrifuging and the lead concentration in the sol estimated by the iodometric method described by Fairhall et al.¹ Using a solution of lead acetate containing 0.4 per cent Pb , approximately 83 per cent of the PbSe formed was in colloidal form.

FIG. 1

In thin layers the sol was a clear brownish-yellow, in thick layers it appeared black. The particles were negatively charged and except for a very small amount of initial sedimentation remained stable. The ultra-filtrate contained a negligible amount of ionic lead, and had a pH ca. 7.0.

It was found, on increasing the concentration of the lead acetate solution above a certain range, that the efficiency of the process was markedly decreased, most of the PbSe being in the form of coarse particles which were removed on centrifuging. These results are contained in Table I. In this and other tables the concentration of colloid is that which would be obtained if the sol were made up to the original volume of lead acetate solution. Using uni-

¹ Medicine Monographs, 7, 25 (1926).

form conditions the results for sols 1-4 were reproducible to within 5 per cent, for the remaining sols larger variations were found in the smaller amounts of colloid formed. The curve in Fig. 1 represents the calculated values.

TABLE I

Sol.	Grms. Lead per 100 cc.		Per cent conversion into colloid

In these cases the NaHCO_3 added to neutralise the solution decreased only slightly the amount of colloid which had been formed prior to its addition. (cf. Table V.)

The factors responsible for the decrease in the percentage conversion into colloid would appear to be concerned with the increased concentration of one or more of the following (1) Pb^{++} , (2) CH_3COO^- , (3) H^+ , (4) CH_3COOH . The results contained in Table II show that acetate ion or undissociated acetic acid in sufficient concentration can inhibit colloid formation. The experimental procedure was similar to that described above. No NaHCO_3 was added in 8 and 9 as no acetic acid was formed. Coarse particles of PbSe were removed by centrifuging.

TABLE II

Sol.	Initial 100 cc. H_2O contain 0.5 gm. gelatin and	Final grms. lead (as colloidal PbSe) per 100 cc.
	1 gm. Lead as	
8. Suspended lead hydroxide		0.2
9. Suspended lead hydroxide, together with sodium acetate at a concn. of 0.1 M		<0.04
	0.3 gm. Lead as	
10. Lead acetate		0.28
11. Lead acetate, together with acetic acid at a concn. of 0.068 M		0.09

Expts. 8 and 9 show the inhibiting effect of the acetate ion in a case where the concentration of Pb^{++} was small and no acetic acid was formed. This behaviour of the acetate ion cannot explain alone the decrease in the amount of colloid formed from the more concentrated solutions of lead acetate, as can be

seen from considering the case of a lead acetate solution containing 1.0 per cent Pb (0.048 M.). When 70 per cent of the lead has been converted into PbSe the percentage ionisation of the acetic acid formed (0.068 M.) would be approximately 2 per cent. If therefore acetate ion alone inhibited colloid formation the remaining 30 per cent of the lead should furnish as much colloid as a solution of lead acetate containing 0.3 per cent Pb. This is not the case. Experiments 10 and 11 show however that acetic acid of concentration 0.068 M. can decrease markedly the amount of colloid formed from a solution containing 0.3 per cent Pb. These experiments can give no information, unfortunately, of any effect of lead ion.

In view of these results it was surprising to find that the sols in Table I were not flocculated by lead acetate, sodium acetate or acetic acid in any concentration. The particles of these sols were negatively charged. It was found that actually during the formation (when passing the H_2Se) the charge was positive, presumably by adsorption of H^+ derived from the acetic acid present. The reversal of the sign apparently takes place on the neutralization of the acetic acid by NaHCO_3 . The positively charged sol before neutralisation (containing excess H_2Se) could also not be flocculated by any concentration of sodium acetate or acetic acid. Since therefore acetate has no effect on the colloid when once formed it seems probable that it influences the process of formation.

The following considerations may be suggested as an explanation.

In the preparation of colloid solutions by condensation methods the governing factors can be considered to be the relative velocities of the formation of nuclei, the growth of the nuclei, and the flocculation of the resulting particles. A large value for the ratio
$$\frac{\text{velocity of formation of nuclei}}{\text{velocity of growth of nuclei}}$$
 will result in the formation of small particles and vice-versa. In the present case it seems that the velocity of flocculation of the resulting particles is negligible. It is generally accepted¹ that the velocities of formation and of the growth of the nuclei are independent, and in the case of gold sols this has been demonstrated by Zsigmondy and his co-workers.² It was shown that the presence of different substances during the reduction could alter one process without affecting the other. Hiege has found that ammonium chloride, potassium ferro- and ferri-cyanides inhibit the formation of nuclei without affecting their velocity of growth. This resulted in the formation of coarser particles. The amount of inhibition (measured by the decrease in the number of particles formed) increased with the concentration of added substance and finally at concentrations considerably less than the flocculation values caused the formation of coarse blue sols. Ammonia which did not flocculate a gold sol showed a similar inhibiting effect when present during the formation of the particles of the gold sol.

¹ Tammann: *Z physik. Chem.*, **25**, 441 (1898); Freundlich: "Colloid and Capillary Chemistry", p. 327 (English Transl.).

² Zsigmondy: *Z. physik. Chem.*, **56**, 65, 77 (1906); Hiege: *Z. anorg. Chem.*, **91**, 145 (1915).

In the formation of PbSe it seemed not improbable that a similar effect was present, i.e. acetate ion or acetic acid reduces the velocity of formation of nuclei without affecting the velocity of their growth and in large concentrations (i.e. with large concentrations of lead acetate) cause the nuclei to grow to particles large enough to be removed by centrifuging.

If all the nuclei in any given case grew finally to the same size of particle the transition from complete colloid formation to complete precipitation as the concentration of lead acetate in the initial solution was increased would be abrupt at the concentration corresponding to the formation of particles large enough to be removed by centrifuging. As this is not so it is assumed that in the final state reached (before centrifuging) the sizes or masses of the particles present are governed by a distribution formula,¹ i.e. each mixture contains particles of all probable masses, and that in unit volume the number whose masses lie between m and $m + dm$ is dn , where

$$dn = \frac{4n}{\sqrt{\pi}} \cdot \left(\frac{m}{\sigma}\right)^2 \cdot e^{-(m/\sigma)^2} \cdot d\left(\frac{m}{\sigma}\right) \quad (1)$$

Here σ is the most probable mass of a particle in the particular mixture in question.

The integral of (1) from $m = 0$ to $m = \infty$ equals n , where n is the number of particles of all degree of dispersion² in unit volume. The mass of the particles lying between m and $m + dm$ is

$$m \cdot dn = dm = \frac{4n\sigma}{\sqrt{\pi}} \cdot \left(\frac{m}{\sigma}\right)^3 \cdot e^{-(m/\sigma)^2} \cdot d\left(\frac{m}{\sigma}\right) \quad (2)$$

The total mass of material present, comprising colloid and non-colloid particles of PbSe is denoted by M and is given by

$$\int_0^{\infty} dm = M = \frac{2n\sigma}{\sqrt{\pi}} \quad (3)$$

When the mixture is centrifuged particles whose mass exceed a certain limit are removed, while all other particles remain in suspension. It is considered that the material remaining in suspension is in colloidal form. The mass of this colloidal material is denoted by M_c and can be evaluated by integrating (2) between the limits $m = 0$ and $m = m_1$, where m_1 has such a value that particles of mass greater than m_1 are removed on centrifuging. Carrying out this integration

$$\begin{aligned} M_c &= \frac{4n\sigma}{\sqrt{\pi}} \int_0^{m_1/\sigma} \left(\frac{m}{\sigma}\right)^3 \cdot e^{-(m/\sigma)^2} \cdot d\left(\frac{m}{\sigma}\right) \\ &= \frac{2n\sigma}{\sqrt{\pi}} \left[1 - e^{-(m_1/\sigma)^2} - \left(\frac{m_1}{\sigma}\right)^2 \cdot e^{-(m_1/\sigma)^2} \right] \\ &= M \left[1 - e^{-(m_1/\sigma)^2} - \left(\frac{m_1}{\sigma}\right)^2 \cdot e^{-(m_1/\sigma)^2} \right] \end{aligned} \quad (4)$$

¹ Nordlund: Kolloid-Z., 26, 121 (1920), using Odén's method has determined the distribution of sizes in a mercury sol. He found that the shape of the distribution curve varied with the method of preparation of the sol, sols prepared electrically giving a curve with the most pronounced maximum.

² The concentration of molecular PbSe present is negligible.

As the initial concentration of lead acetate is increased the most probable mass σ of a particle must also increase to account for the decreased fraction (M_c/M) converted into colloid.

For the present purpose the upper limit of the diameter of a colloid particle (mass m_1) is taken as 0.2μ . Assuming that the particles are spherical and of density 8 (approximately the density of lead sulphide) the upper limit of the mass m_1 will be

$$m_1 = \frac{4}{3} \pi r_1^3 \rho \quad \text{where } r_1 = 0.1 \mu \\ = 3.35 \times 10^{-14} \text{ grams.}$$

To evaluate (4) for each initial concentration of lead acetate it is necessary to know σ for each case. This can be obtained from equation (3) if n , the total number of particles (prior to centrifuging) can be determined in each case.

Now the velocity of nuclei formation and hence the number of particles finally formed depends on the concentration of acetate ion or acetic acid present. If therefore a relation could be established from other data between the concentration of inhibiting substance and the number of particles and applied to the present case the required values of σ could be obtained without a knowledge of n . This procedure has been adopted in the following.

As already mentioned, Hiege has determined the total number of gold particles (of all degrees of dispersion since in this case all the particles remained in colloid solution) formed in a reduction mixture containing various concentrations of NH_4Cl . It has been found that Hiege's data fit an empirical equation of the form

$$\log_e n_o/n = ac^b \quad (5)$$

where n_o is the total number of particles finally formed in the absence of NH_4Cl , n is the total number of particles finally formed in the presence of a concentration c of NH_4Cl (in micromols per litre) and a and b are constants. Table III contains Hiege's data and the values calculated from equation (5).

TABLE III
Flocculation value of $\text{NH}_4\text{Cl} = 27000$ micromols per litre
 $a = 0.0444$; $b = 0.562$

Concn. NH_4Cl micromols/litre	No. of particles obsvd. in $217\mu^3$	No. of particles calculated
0	$90 = n_o$	—
38	64	64
76	52	54
230	36	35
380	26	26

In the case of $\text{K}_3\text{Fe}(\text{CN})_6$ where only two values (apart from n_o) are given the exponent b equals 0.61.

The relation found to hold for the results of Hiege is now applied to the present case. It is assumed that the inhibiting effect of acetate ion and acetic

acid is the same,¹ hence they can be considered as one substance with a constant concentration equal to the concentration of acetate ion present at the commencement of the reaction. For the present purpose it must also be assumed that the lead ion is ineffective.

Expressing equation (5) in the form

$$n = n_0 \cdot e^{-ac^b}$$

where n_0 is the number of particles which would be formed if the process could be carried out in the absence of acetate and substituting the above value of n in equation (3) it follows that

$$\sigma = \frac{M\sqrt{\pi}}{2n_0 \cdot e^{-ac^b}} \quad (6)$$

the weight of the n_0 particles being M . The term M/n_0 is the average mass of the particles which would be formed if the process could be carried out in the absence of acetate. It may reasonably be assumed that if twice the amount of lead were used in the absence of any inhibiting substance twice the number of particles would be formed, i.e. M/n_0 is constant. Thus

$$\sigma = k \cdot e^{-ac^b} \quad \text{When } c = 0 \\ k = \sigma_0$$

$$\text{Hence } \log_e \frac{\sigma}{\sigma_0} = ac^b$$

By a suitable choice of the constant σ_0 , a and b such values of σ were obtained (in terms of the concentrations c of acetate) that on substituting them in equation (4) results for the percentage conversion into colloid were obtained. These have already been given in the final column of Table I. The equation was used in the form

$$\log_e \frac{\sigma}{\sigma_0} = 4.95 \times 10^{-4} \cdot c^{1.89} \quad (7)$$

where $\sigma_0 = 1.175 \times 10^{-14}$ gram. and c is the total concentration of acetate (acetate ion and acetic acid) in millimols per litre present during the reaction. As should be the case σ_0 (the most probable mass of a particle in the hypothetical case of formation in the absence of acetate) is less than m_1 (3.35×10^{-14} gram.), the upper limit of the mass of a colloid particle of PbSe.

It should be pointed out that these results furnish only indirect support of the theoretical explanation advanced concerning the decreased yield of colloid as the concentration of the initial solution of lead acetate is increased. Given the distribution of particle mass assumed it has been shown that a relation which holds for the results of Hiege on what is believed to be a related phenomenon likewise holds for the experimental results obtained with lead selenide.

From equations (6) and (7) we have already seen that

$$\begin{aligned} \frac{M\sqrt{\pi}}{2n_0} &= \sigma_0 \\ &= 1.175 \times 10^{-14} \text{ gram.} \end{aligned}$$

¹ Compare sols 9. and 11. in Table II.

$$\begin{aligned}\text{But } \frac{M}{n_0} &= m_0 \\ &= \frac{4}{3} \pi r_0^3 \rho \\ &= \frac{2\sigma_0}{\sqrt{\pi}}\end{aligned}$$

Hence $r_0 = 73\mu\mu$.

M/n_0 is the average mass of the particles which would be formed in the absence of any inhibiting substance, and r_0 is the radius of the average particle. If the upper limit of the radius of a colloid particle had been assumed to be 0.05μ instead of 0.1μ , r_0 would have been $37\mu\mu$. These values are not unreasonable.

In equation (5) relating the number of particles formed to the concentration of inhibiting substance the exponent required, viz.—1.89, is considerably greater than in the case of the gold sol although with PbSe a protective agent is present. A similar equation was used by Marc¹ to express the influence of foreign substances on the velocity of crystallization of supersaturated solutions, the decrease in velocity ($\log v_0/v$) being proportional to the amount adsorbed. In the present case ac^b can hardly represent adsorption since b is greater than unity. It does not seem probable on general grounds that the effect of foreign substances on nuclei formation would be connected with adsorption.

Alternative Method of Preparation of Lead Selenide Sol

As the above method could not give sols containing more than approx. 0.34 per cent Pb (as PbSe) solid lead carbonate was suspended in the initial solution of lead acetate and gelatin. During the passage of H_2Se , assuming a sufficiently rapid solution of $PbCO_3$ in the acetic acid formed, the concentration of lead acetate should remain constant as long as any $PbCO_3$ remained. By this method the amount of lead present could be increased without increasing the concentration of anion above a value which would result in the inhibition of colloid formation. After the disappearance of the $PbCO_3$ and the passage of excess H_2Se sufficient $N/2$ $NaHCO_3$ was added to neutralise the acetic acid present. The procedure was then the same as that previously described.

TABLE IV
Grms. lead per 100 cc.

Sol	Initial mixture as lead acetate	as lead carbonate	Final as colloidal lead selenide	Per cent conversion into colloid	Revs. per min.
12	0.35	0.31	0.09	14	1300
13	0.35	0.31	0.246	37	800
14	0.35	0.31	0.429	65	300
15	0.35	0.62	0.156	16	1300
16	0.35	0.62	0.490	51	300

¹ Marc: Z. physik. Chem., 73, 685 (1910).

It was found that a very rapid rate of stirring decreased markedly the amount of colloid formed. The results are given in Table IV, the approximate rates of stirring are in the sixth column. With the slow rate of stirring the disappearance of the PbCO_3 was very slow (requiring approx. 36 hours.)

The expected conversion into colloid was 90 per cent (cf. sol. 3, Table I). In three cases the amount of colloid was less than that which would have been obtained from the lead acetate solution alone, (approximately 0.32 per cent Pb as PbSe). In these three cases it was found that a decrease in the amount of colloid present took place after the addition of the $\text{N}/2 \text{ NaHCO}_3$. In Table V are given the concentration of colloid in sols 13, 14 and 16 before addition of NaHCO_3 (determined by withdrawing a portion of the sol containing excess H_2Se before the addition and centrifuging) and in the neutralised sols after removing H_2Se in the usual way. For comparison similar figures for a lead acetate solution containing no PbCO_3 are given.

TABLE V

Sol	Initial total grms. lead per 100 cc.	Grms. Pb as colloidal PbSe		Fraction pptd. by NaHCO_3	Revs. per min.
		Before addtn. of NaHCO_3	After addtn. of NaHCO_3		
13	0.66	0.415	0.246	0.41	800
14	0.66	0.439	0.429	0.02	300
16	0.97	0.493	0.490	0.01	300
Lead acetate	0.35	0.318	0.283	0.11	800
alone	0.35	0.323	0.315	0.03	300

It will be seen that the fractional decrease in the amount of colloid following the addition of NaHCO_3 is only appreciable in the case of rapid stirring. The influence of stirring on the process of flocculation has been considered by Smoluchowski¹ and found to increase rapidly with the size of the particles, the effect becoming considerable when some of the particles approach macroscopic size. In the experiments with a mixture of lead acetate and carbonate there is a considerable amount of PbSe present in non-colloid form (given by the difference between columns 2 and 3 in Table V) before the addition of NaHCO_3 . This addition reverses the sign of the charge on the colloid particles and it may be assumed that they have a minimum stability at the isoelectric point. It seems not improbable therefore that rapid stirring in the presence of macroscopic particles of PbSe would remove some of the colloid at this point. This is in agreement with the much smaller effect of rapid stirring when lead acetate alone was used (cf. Table V); here the amount of non-colloid PbSe was also small.

¹ Smoluchowski: *Z. physik. Chem.*, **92**, 129 (1917), considered a stationary particle and calculated the ratio of the number of particles brought within its sphere of attraction by stirring and by Brownian movement.

The matter appears to be more complex than the above explanation would suggest. It can be seen for example from Table V, column 3, that rapid stirring decreases somewhat the amount of colloid present before NaHCO_3 is added.¹ Further it was found if a rapid rate of stirring was maintained until the addition of NaHCO_3 and slowed down during and after the addition that the decrease in the amount of colloid due to the addition of NaHCO_3 was greater than if the whole process had been conducted at the slower rate of stirring. This is difficult to reconcile with the explanation given in the preceding paragraph. Further investigation is required on these points.

From Table V it can be seen that the yield of colloid was less than the expected value (90 per cent) even before the addition of NaHCO_3 . Because of the slow rate of solution of PbCO_3 in the acetic acid formed, H_2Se accumulated in the mixture before the PbCO_3 had disappeared. Direct reaction of H_2Se with the surface of the particles of PbCO_3 giving lead selenide in non-colloid form would explain the low yield of colloid obtained.

Lead Selenide Sols of High Concentration

It was possible to concentrate a lead selenide sol by long continued boiling. A more convenient method was to add an equal volume of a saturated solution of ammonium sulphate. This precipitated the gelatin in the form of black flocks containing all the lead selenide. On washing free from ammonium sulphate with cold water, the precipitate could be redispersed in warm water to give stable sols of any desired concentration. Owing to the simultaneous increase in the amount of gelatin the more concentrated sols set to stiff gels on cooling.

Summary

I. Two methods for the preparation of lead selenide sols are described using gelatin as a protective agent

- (a) from lead acetate.
- (b) from a mixture of lead acetate and lead carbonate.

2. With the first of these methods the percentage transformation into colloidal lead selenide rapidly decreased as the initial concentration of lead acetate was increased above a certain limit. This effect could be attributed to the presence of acetate ion or acetic acid into which the acetate ion is mainly transformed. As these had no precipitating action on the colloid when once formed it was concluded that the effect was exerted during the process of formation.

3. It is suggested that acetate ion or acetic acid decrease the velocity of formation of nuclei whilst leaving unaltered the velocity of growth of the nuclei. Above a certain concentration the disparity in these velocities is sufficient to produce particles of non-colloid (macroscopic) dimensions. A quantitative treatment has been attempted.

¹ Freundlich and Kroch: *Z. physik. Chem.*, **124**, 155 (1926) have studied the coagulation of a CuO sol by stirring alone. They found that this coagulation was not accompanied by any change in the electro-kinetic potential of the particles.

4. With the first method of preparation the rate of stirring had a small effect on the amount of colloid formed. On the other hand with the second method a very rapid rate of stirring decreased markedly the yield of colloid. A provisional explanation is advanced.

5. A method for obtaining a colloidal solution of lead selenide of high concentration is described with gelatin as stabilising agent.

In conclusion the writer wishes to express his best thanks to Professor W. C. M. Lewis, F.R.S. under whose direction this work was carried out, and to Dr. M. Jowett for many valuable suggestions.

A CRYOSCOPIC STUDY OF BENZENE SOLUTIONS

BY J. MERRIAM PETERSON¹ WITH WORTH H. RODEBUSH

It has been common knowledge for a long time that some substances, for example acetic acid, appear to have a higher molecular weight (as estimated from vapor pressure lowering) in benzene solutions than in water solutions. Since water has a well known "ionizing" action it may also be suspected of a dissociating action on neutral polymerized molecules and is usually classed as a "dissociating" solvent. In contradistinction benzene is often designated as an "associating" solvent. In view of the known fact that acetic acid has an abnormally high vapor density and that it can be shown theoretically that all molecular weight results even in solution refer to the density of the vapor it may be questioned whether benzene behaves in any way except as an inert solvent.

Another point which requires consideration is that high results for molecular weights obtained by the cryoscopic method might be due to deviations from ideal solution conditions and not to association at all. These questions can best be answered by obtaining complete data for the partial pressures of solvent and solute. Since it is necessary to work in dilute solution in order to apply any of the laws of solution at all, sufficient accuracy cannot be obtained by direct measurement of partial pressures and it is necessary to use the indirect cryoscopic method, which is equivalent to measuring the vapor pressure of the solvent only.

Theoretical

The fundamental law of solutions for changes in composition at constant temperature and pressure is due to Gibbs²

$$m_1 \frac{\partial \bar{F}_1}{\partial m_2} + m_2 \frac{\partial \bar{F}_2}{\partial m_2} = 0 \quad (1)$$

$$\text{where } \bar{F}_1 = \frac{\partial F}{\partial m_1}, \bar{F}_2 = \frac{\partial F}{\partial m_2}$$

Here m_1 and m_2 are the masses in grams of the respective constituents of the solution and F is the total free energy of the solution. If the free energies of the pure constituents are arbitrarily taken as zero then F is the free energy change on mixing. Equation (1) is simply a mathematical statement of the fact that the free energy of mixing depends only on the final amount and composition of the solution. The Duhem-Margules equation is derivable from (1) if the vapors are perfect gases.

The unit of mass is taken as the gram in order that the introduction of the concept of molecular weight may be scrutinized more carefully.

¹ This is an abstract of a thesis submitted by J. M. Peterson in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

² Gibbs: "Scientific Papers," 1, 88 (1906).

If the subscript 1 refers to the solvent we may evaluate the first coefficient of (1) in terms of freezing point lowering. For equilibrium between the solvent in solution and the pure solid solvent we have:

$$\frac{\partial \bar{F}_1}{\partial T} dT = \frac{\partial \bar{F}_1}{\partial T} dT + \frac{\partial \bar{F}_1}{\partial m_2} dm_2 \quad (2)$$

This equation (2) transforms into:

$$\frac{\partial \bar{F}_1}{\partial m_2} = \frac{\Delta H_f}{T_f} \frac{\partial T}{\partial m_2} \quad (3) \text{ since } \frac{\partial F}{\partial T} = -S, \Delta S_f = \frac{\Delta H_f}{T_f}$$

Here ΔH_f is the heat of fusion per gram of the solid solvent into solution. In dilute solution we may assume ΔH_f independent of concentration and neglect the temperature coefficient of \bar{F}_1 . Substituting in (1) which is strictly an isothermal equation.

$$m_1 \frac{\Delta H_f}{T} \frac{\partial T}{\partial m_2} + m_2 \frac{\partial \bar{F}_2}{\partial m_2} = 0 \quad (4)$$

The appearance of dT in an isothermal equation need cause no concern since it represents the *amount by which the temperature of the solution would be changed if its freezing point were measured*. The best physical measurable quantity to use in expressing the second coefficient of (1) is the partial pressure of the solute. We have

$$m_2 \frac{\partial \bar{F}_2}{\partial m_2} = m_2 V_2 \frac{\partial p_2}{\partial m_2} = \frac{m_2}{\rho} \frac{\partial p_2}{\partial m_2}$$

Where ρ is the density and V_2 the specific volume of the solute vapor. Substituting in (4) we have

$$M_1 \frac{\Delta H_f}{T} \frac{\partial T}{\partial m_2} + \frac{m_2}{\rho} \frac{\partial p_2}{\partial m_2} = 0 \quad (5)$$

So far nothing has been said of molecular weight. The apparent molecular weight M is defined for a gas by the equation

$$M = \frac{\rho R T}{p}$$

where R is expressed in appropriate units. Combining (5) and (6) we have

$$M = - \frac{RT^2}{m_1 \Delta H_f} \left(\frac{\partial \ln p_2}{\partial \ln m_2} \right) \left(\frac{\partial m_2}{\partial T} \right) \quad (7)$$

It is necessary in order to calculate M from freezing point lowering data alone to make some assumption as to the relation of p_2 and m_2 . We may assume that Henry's law $p_2 = kx_2$ where x_2 is the mol fraction of the solute, holds for normal solutes in dilute solution. If the solution is dilute this may be written $p_2 = k.m_2$ and (7) becomes

$$M = - \frac{RT^2}{m_1 \Delta H_f} \frac{\partial m_2}{\partial T} \quad (8)$$

It is common practice to substitute $m_2/\Delta T$ for $\partial m_2/\partial T$ where ΔT is the freezing point lowering but this is only justified if the lowering is a linear function of m_2 . The equation (8) connecting freezing point lowering with molecular weight is not usually given in the exact form and it is important to rec-

ognize its exact significance. Provided the assumption of Henry's law is justified, we can calculate the *apparent molecular weight* as defined by eq. (6) in the vapor state, for the solute. The vapor is not assumed to be a perfect gas. If Henry's law does not hold the calculations will be in error. It is important to note that the proper value of $\partial m_2/\partial T$ must be used for a given concentration. It cannot be emphasized too strongly that a molecular weight, as determined in solution by freezing point lowering, depends only upon the vapor density of the solute and not upon the vapor density of the solvent.¹ Several questions are at once suggested by the above statement. What does a molecular weight mean for a nonvolatile solute, and how can a solute have different molecular weights in different solutions? A molecular weight determination for a nonvolatile solute gives us a hypothetical vapor density. If a solute does not give the same molecular weight in different solutions then one of two things must be true. Either the solute has a variable molecular weight in the vapor state depending on the pressure e. g. acetic acid vapor, or the assumption of Henry's law is not justified. If Henry's law does hold and a solute shows different molecular weights in different solvents at the same concentration the partial pressures over the different solutions must be different to account for the variable vapor density indicated. This may imply a different state of association in the various solvents but it does not give any exact information.

FIG. 1

It is impossible to avoid some uncertainty as to the amount of error involved in the assumption of Henry's law. Even in the case where the freezing point lowering is a linear function of the concentration so that $\partial m/\partial T$ is constant it does not follow that Henry's law holds, unless the apparent molecular weight of the solute in the vapor state is likewise known to be independent of concentration. In general, Henry's law cannot hold for an associated solute. At the extremes of concentration however, where the dissociation is either slight or nearly complete Henry's law may hold. In solutions of appreciable concentration the deviation from Henry's law will depend, in the simple cases at least, on the deviation of the Henry's law constant from the ideal solution constant.¹ This will be evident from Fig. 1 where the dotted line indicates the ideal solution partial pressure and the heavy lines the partial pressures for typical solutions. For positive deviations at any point $\partial p_2/\partial m_2$ will be less than p_2/m_2 , while the reverse will be true for negative deviations. We have the identity

¹ Contrast with J. Kendall: J. Am. Chem. Soc., 43, 1391 (1921).

$$\frac{\partial \ln p_2}{\partial \ln m_2} = \frac{\partial p_2 / \partial m_2}{p_2 / m_2}$$

If $\partial p_2 / \partial m_2 < p_2 / m_2$ then the use of the simplified form (8) will lead to too large a value for the molecular weight. For positive deviations from ideal solutions then we may expect too large a value of the molecular weight in all except extremely dilute solutions. A negative deviation will produce the reverse effect. These theoretical considerations will be referred to later in connection with the data obtained in this work.

FIG. 2

Experimental

A number of the earlier workers with the cryoscopic method obtained data on benzene solutions. Prominent among these are Raoult,¹ Beckman,² Auwers,³ Paternò,⁴ and Rozsa.⁵ All of this work, however, was done with mercury thermometers and comparatively crude apparatus, so that a high percentage accuracy could not be obtained in dilute solution where Henry's law may be assumed to hold. In the work described in this paper the greatest lowering measured was 0.257°C.

Apparatus: The apparatus consisted essentially of two freezing point bulbs A and B Fig. 2 which were placed in Dewar tubes. In the top of the bulbs were openings for the insertion of the thermocouple, air bubbling tube, pipette, etc. These openings were made tight by perforated corks which had been extracted with benzene. This part of the apparatus was enclosed in a

copper can which was nearly submerged in a water thermostat. The cover of heavy sheet copper was above the water level but this has been shown to give satisfactory temperature equilibrium.¹ The thermostat was heavily insulated, cooled by the ice box H and heated by the lamp L. A conventional type of mercury regulator was used and no difficulty was experienced in maintaining any temperature between 5° and 25°C with variations less than 0.01°.

The thermocouple was a ten-junction copper-constantan couple of resistance 54.2 ohms and a calibrated e.m.f. of 396.6 microvolts per degree at the freezing point of benzene. The e.m.f. was read on the self-calibrating potentiometer devised by Rodebush,² with a precision of 0.02-0.03 microvolt.

Experimental Procedure

The apparatus was designed originally with the expectation of following the experimental procedure used by Hovorka and Rodebush on dilute water solutions. Surprising difficulties were met with however because of the peculiar waxy nature of solid benzene. It cannot be broken up into conveniently sized particles, as can ice, nor can it be handled in contact with the air because of the absorption of moisture which produces a marked change in the freezing point. In order to get a satisfactory temperature equilibrium in freezing solutions it is necessary to have a mush of fine solid particles in contact with liquid. The ordinary laboratory method of producing this mush by supercooling did not produce enough of the solid to cover the thermocouple to a satisfactory height. This method was actually used with some success, by supercooling the benzene very markedly and it is probably the simplest and best method, but one day it suddenly became impossible to supercool benzene more than a degree in the laboratory and the method had to be abandoned. This sort of experience is of course a common occurrence in crystallization work.

It became necessary therefore to devise a new procedure of obtaining a mush of solid benzene. The method finally adopted was as follows:

The freezing point tubes were filled with pure benzene, stoppered, and placed in a beaker of ice water until a thin layer of solid had formed on the sides of the tube. The tube was then removed and warmed slightly with the hand whereupon, on shaking, small particles of solid benzene would break loose from the sides and settle to the bottom of the tube. By repeating this process a satisfactory amount of solid free from contamination was produced. The temperature equilibrium obtained was not as perfect as can be had with ice and water but it was usually constant within 0.001°.

When a sufficient amount of solid had been obtained in two tubes they were placed in the thermostat and the thermocouple and the various connecting tubes inserted. The tube B served as the standard temperature bath for the thermocouple while the benzene was withdrawn from A through the bubbling tube C. The solid benzene in A was rinsed free of pure benzene by introducing small quantities of the solution from F and withdrawing it through

¹ White: J. Am. Chem. Soc., **48**, 1149 (1926).

² Hovorka and Rodebush: J. Am. Chem. Soc., **47**, 1614 (1925).

C. When this had been repeated several times the tube A was filled with solution and equilibrium obtained by bubbling purified air saturated with benzene vapor through both tubes. All the solutions were handled out of contact with the air or any possible source of contamination. The solutions were made up by direct weighing. The small amounts of solute were sealed in glass bulbs for weighing and the bulb broken beneath the surface of a weighed amount of benzene, to make up the solution.

FIG. 3

Preparation of Materials: Benzene. Very pure benzene may be obtained because of the possibility of freeing it from most of its impurities by fractional crystallization or freezing. Thiophene, it is true, cannot be separated in this way but this impurity can easily be removed chemically. On the other hand, paraffin hydrocarbons, olefins, acetone and most other impurities are quickly eliminated from the successive crop of crystals.

Mallinckrodt's best grade of thiophene-free, pure benzene was used. This was fractionally crystallized 5 times discarding about one-tenth of it each time. It was then fractionally distilled twice, using a tall, efficient, fractionating column, the last time from phosphorus pentoxide directly into the freezing point tubes. The distilling apparatus as well as the tubes were thoroughly dried, by a stream of dry air, immediately before use and were protected during the distillation by a phosphorus pentoxide tube. The first benzene dis-

tilling over was never used and the last portion in the flask was never distilled. The boiling point of the benzene used varied less than .02 degree C. Further treatment appeared to have no effect upon the freezing point.

Acetic acid. Kahlbaum's acetic acid labeled "100 percent" was used. This was recrystallized 5 times and fractionally distilled from a small amount of phosphorus pentoxide. Only the middle fraction was collected for use. Altho the very constant reading of the thermometer would not indicate any acetic anhydride in the distillate, this possibility was eliminated by a further purification by freezing.

Water. "Conductivity" water was used.

Methyl alcohol. A c.p. grade of methyl alcohol was used which was dried with magnesium methyrate and fractionally distilled.

Ethyl alcohol. Absolute ethyl alcohol was further dried with magnesium ethylate and fractioned.

Benzoic acid. The purity of the benzoic acid used was certified by the Bureau of Standards. It was recrystallized and dried in a vacuum desiccator.

Toluene. The toluene was prepared by the acid hydrolysis of p-tolyl sulfonic acid. The resulting product was fractionated.

Results: The results are given in Table I and are shown graphically in Fig. 3. It will be noted that the freezing point depression appears to be a linear function of the weight of solute per 1000 gms. of benzene for all of the substances except acetic acid and methyl alcohol. The results in the case of ethyl alcohol are not sufficiently consistent to determine absolutely that no curvature exists but a straight line fits the data as well as any curve that could be drawn. In the case of the other solutes there can be no doubt, in dilute solution at least, as to the linear relation. There appear to be no data in the literature of high accuracy for very dilute solutions of the substances we have investigated except in the case of water. Richards, Carver and Schumb¹ determined the freezing-point depression of benzene saturated with water to be 0.095°C which is close to our value of 0.0987°C . We find by extrapolation that the solubility of water at the freezing point is 0.35 gm. per 1000 gms. of benzene.

The toluene solutions were studied with the special purpose of determining the so called "molal freezing point" constant for benzene. Since even in the case of Henry's law can not be assumed except as a limiting law results were obtained only in very dilute solutions. The value obtained in this way is 5.11 but the experimental error makes the last figure uncertain. The value calculated by equation (8) from the heat of fusion of benzene is 5.07 but the most probable heat of fusion 30.4 cal/gm as estimated from numerous determinations in the literature must be uncertain by $\frac{1}{2}$ percent.² The value which we shall adopt 5.10 appears to give satisfactory values for the apparent molecular weights at infinite dilution for the various solutes and is probably not in error by more than one percent.

In Fig. 4 the values of $\partial m/\partial T$ for the various solutes are plotted against the freezing point lowering. The values of $\partial m/\partial T$ are obtained by graphical methods from the curves of Fig. II and are of course not of high accuracy except in the cases where the curve is linear. Since, assuming Henry's law, the apparent molecular weight is $5.1 \times \partial m/\partial T$ this quantity is also shown on the left side of Fig. 3. It should be noted in advance that an apparent molecular weight greater than the formula weight is easily accounted for as due, either to association or positive deviation from the ideal solution law, while a value less than the formula weight probably means error in the value estimated for $\partial m/\partial T$ since negative deviations from the ideal solution law are not probable. In the case of water and ethyl alcohol the apparent molecular weights are independent of concentration and equal respectively to 18.1 and 46.4 indicating no appreciable association of the vapors. Some association is indicated in the case of methyl alcohol and the limiting value of 31.1 may be due to error or to one of the causes noted above. The case of acetic acid is that of a typical associated vapor. The value of 59 at infinite dilution is probably too low because of error in extrapolation. Undoubtedly acetic acid vapor is completely depolymerized at low pressures and approaches the double for-

¹ Richards, Carver and Schumb; J. Am. Chem. Soc., 41, 2019 (1919).

² See Landolt-Börnstein-Roth: "Tabellen."

mula at high pressures. Our measurements cover practically the entire range from complete dissociation to complete association but it is only at the lower limit of concentrated that Henry's law may be assumed to be anything more than a rough approximation. Molecular weights calculated over the rest of

FIG. 4

the range measurements must be regarded as approximations only. The case of benzoic acid is somewhat different. At the higher concentrations the vapor density corresponds to the double formula or even a greater degree of association, while the measurements have not been carried to sufficiently low concentrations to show the complete dissociation as in the case of acetic acid. The extrapolation to zero concentration is without significance. Henry's law cannot be assumed to hold in any part of the measured range except as a rough approximation. In view of the small vapor pressure of benzoic acid it is seen that the polymerized molecule of benzoic acid is a far more stable affair than the polymerized acetic acid molecule.

From the foregoing considerations one may draw the conclusion that for all of the solutes investigated, except benzoic acid, Henry's law holds at least in the more dilute solutions; and that where the freezing point depression indicates polymerization an abnormal vapor density actually exists. The latter conclusion is, as shown in the beginning of this paper by thermodynamic reasoning, a necessary consequence if the first is true.

Summary

An exact equation has been derived from thermodynamics, which relates the freezing point depression of a dilute solution to the vapor density of the solute.

Data are given for the freezing point lowerings of dilute benzene solutions for a number of solutes.

The vapor densities of the solutes are calculated from the freezing point data.

Urbana, Illinois.

THE SYNTHESIS OF WATER OVER NICKEL AND COPPER CATALYSTS. THE MIXTURE EFFECT AND PROMOTER ACTION

BY FRANCIS E. SMITH

It has been shown in a previous paper¹ that the mechanism of the catalytic synthesis of water vapor is essentially the same for both nickel and copper catalysts. Starting in each case with metal prepared by reducing the oxide in the form of porous granules, the results showed that the catalytic reaction consists of two separate stages. The first, or initial, stage is characterized by a relatively high rate of synthesis, a relatively low, or zero, rate of leakage of free oxygen gas past the catalyst, and the gradual covering of the reduced metal by a layer of oxide. The spreading of this oxide over the catalyst can be followed visually in the case of copper, and with both metals by the temperature effects produced at the oxide-metal boundary. The second stage in the catalytic reaction follows the covering of the catalyst by this stable oxide. It is characterized by a lower rate of synthesis, a much higher rate of oxygen leakage, an extremely slow rate of formation of further oxide, and the absence of further temperature effects. The separation of the two stages is less distinct with copper than with nickel, but the general similarity of behavior in the two cases is quite evident.

It should be emphasized that only in the second stage is there what may be called "true" catalysis, and that the initial stage is really "catalysis with destruction of the catalyst." Whether this destruction is necessary to the synthesis in the first stage, or whether it is the result of a side reaction which plays little or no part in the catalysis, was not definitely shown by the then existing data, but the latter hypothesis seemed the more probable.

The interpretation given these experimental results was that the catalytic mechanism involved a fast reaction between an "indefinite" oxide and hydrogen, and that this was inhibited by the covering of the catalyst by the layer of oxide. This interpretation can be stated equally well by saying that it involves the alternate, or more probably simultaneous, formation of an "indefinite" oxide and its reaction with hydrogen. In view of the proved inhibiting action of free gaseous oxygen on the reduction, but little importance was attached to the possibility of a mechanism involving alternate reduction of the stable oxide and reoxidation of the metal surface thus exposed, a mechanism first proposed by Pease and Taylor² for the catalysis with copper. These authors postulated, on the basis of preliminary observations, an entirely different mechanism for the catalysis with nickel. Our results showed, however, that the behavior of these metals is essentially the same, and that the most probable mechanism for one must be that for the other. In the

¹ Larson and Smith: *J. Am. Chem. Soc.*, **47**, 346 (1925).

² Pease and Taylor: *J. Am. Chem. Soc.*, **44**, 1637 (1922).

Fourth Report of the Committee on Contact Catalysis,¹ the interpretation of the results for both nickel and copper given in our paper is accepted by Taylor in preference to the mechanism involving the stable oxide.

Benton and Emmett,² however, in an article on the water synthesis over nickel, attempt to show that the stable oxide is an essential step in the catalytic mechanism. While there is no disagreement regarding the experimental facts, the conclusions reached by these authors appear to be unjustified. Their interpretation will be discussed in a later section.

The present paper gives the results of further experiments with pure nickel and copper catalysts, and extends the investigation into the field of mixed and promoted catalysts. Evidence is presented to show that the physical nature of the catalyst surface, as well as its chemical properties, is of primary importance in determining the catalytic activity. The results are, in general, consistent with the theory of the catalytic mechanism given in the first paper, and are presented as further support for it.

Preparation of Catalytic Material

All the catalysts used in the present work, with but one exception, were prepared by reduction in hydrogen of the precipitated hydroxides, following the procedure described in the first paper.³ These precipitated hydroxides, which were in the form of porous granules of 8-14 mesh size, varied somewhat in hardness. In the copper-nickel series there was a gradual increase in hardness from pure copper to pure nickel. The copper-alumina was more firm than the corresponding copper, and pure nickel was firmer than copper-alumina. Of the two precipitated copper hydroxides, that in the copper-nickel series was less hard than that in the copper-alumina.

The one exception to the method of preparation by precipitation was in the case of a fused copper oxide.⁴ Electrolytic copper wire was roasted in a rotating furnace through which a current of air was passed. The resulting oxide was fused in an electrically heated furnace in the presence of oxygen. After cooling, the fused mass was crushed and screened to 8-14 mesh. The oxide granules were hard and dense, and were black in color. Analysis showed a copper content of 87.3 per cent., corresponding to the composition: 19.6 per cent. cupric, and 80.4 per cent. cuprous oxide.

The preliminary treatment and reduction of the catalyst material were carried out *in situ* as described in the first paper. The reduction at 218° was continued, as in the previous work, until analysis of the effluent gas by passage thru phosphorus pentoxide weighing tubes, showed that it contained less than 0.1 mg. of water per 6 liters of gas. Evidence that the reduction of the porous oxides was complete is presented in the next paragraph.

Samples of the catalysts, after reduction at 218° and operation (as described later) at temperatures not exceeding 184°, were heated at 444° in a

¹ Taylor: J. Phys. Chem., **30**, 157-8 (1926).

² Benton and Emmett: J. Am. Chem. Soc., **48**, 632 (1926).

³ Larson and Smith: J. Am. Chem. Soc., **47**, 346 (1925).

⁴ This oxide was prepared at the Fixed Nitrogen Research Laboratory, Washington, D.C.

stream of pure hydrogen for one-half hour. Additional water was obtained in only two cases,—fused copper¹ gave 31.4 mg., and copper-alumina, 3.6 mg. In the latter case, the water was undoubtedly derived from hydrated aluminum oxide, since dehydration of this oxide is not complete at 218°. The fused copper oxide was not completely reduced at 218°, and fused nickel oxide would no doubt have behaved similarly. This behavior is easily explained as due to the non-porous nature of the granules, which prevented ready access of hydrogen to the interior oxide. However, the evidence is conclusive that the porous oxides obtained from precipitated hydroxides can be completely reduced by hydrogen at temperatures as low as 218°.

Table I gives the compositions by weight of the reduced catalysts, as calculated from analyses of the original granules. No account is taken of the presence of some oxide in catalyst No. 3, the fused copper, nor of the presence of water in combination with alumina in catalyst No. 2b.

TABLE I
Compositions of the Catalysts, per cent. by weight

	Catalyst	Copper	Nickel	Alumina
1a	Copper	100	—	—
1b	Copper-Nickel	88.2	11.8	—
1c	Nickel-copper	25.5	75.5	—
1d	Nickel	—	100	—
2a	Copper	100	—	—
2b	Copper-alumina	95.5	—	4.5
3	Fused copper	100	—	—

The amounts of shrinkage of the different oxides during the preliminary treatment and reduction varied within rather wide limits. The precipitated coppers shrank most of all, while pure nickel, fused copper, and copper-alumina shrank least. The copper-nickel mixtures were intermediate between pure copper and pure nickel in this respect. The volumes of freshly reduced catalyst were in general about 3 cc. This smaller volume as compared with that used in the previous work (7-9 cc.) was found desirable in order to decrease the lengths of the runs, and in particular the lengths of the initial stage in the catalysis. With continued use some further decrease in volume was usually observed, but at no time was the amount of catalyst less than 2 cc.

Experimental Part

The apparatus, shown diagrammatically in Fig. 1, was similar to that used in the previous work, except that no provision for humidification of the gases was made. The final drying of the gases was effected by their passage thru tubes of phosphorus pentoxide and fused potassium hydroxide. Oxygen was added to the hydrogen from the electrolytic cell (1), and its concentration was

¹ The expression "fused copper" will be used to designate the catalyst prepared by reduction of fused copper oxide. Similarly, "precipitated copper" will mean a catalyst prepared from the precipitated hydroxide. When no distinguishing adjective is used in this connection, the precipitated catalyst will be meant.

kept constant at 10 mg. water-equivalent per 5 minute interval. The flow of hydrogen was 100 cc. per minute (0° , 760 mm.). Weighings of the water in the effluent gas were made at suitable intervals, and when desired, the rate of oxygen leakage was determined as in the previous work. Further details are given in the first paper.

Some of the runs were continued over a period of many days, and the catalyst had to be left standing over night. It was found possible to do this with little or no reduction of the stable oxide, if the completely oxidized catalyst was cooled rapidly to room temperature and shut off under a slight excess pressure of the mixed hydrogen-oxygen gases. The following morning the

FIG. 1
Apparatus

catalyst was flushed at room temperature with the mixed gases for about 10 minutes, and was then heated rapidly to the temperature used the previous day. In most cases but little water vapor had accumulated during the overnight period, and there was no great amount formed on heating. It was thus possible to make "continuous" runs without reduction of the oxide. When a run had been completed, the oxide present on the catalyst was determined by shutting off the oxygen and passing pure hydrogen over the catalyst, final reduction being carried out in all cases at 184° . Subsequent heating at higher temperatures up to 444° , as already described, showed that the oxide formed during catalysis can be completely removed in this way.

Experimental Results

Typical results of the present series of experiments are shown in Figs. 2 and 3. Fig. 2 shows the character of the initial stage of the catalysts for the different catalysts, while in Fig. 3 efficiencies of conversion in the final steady state are plotted against temperature.

As the curves of Fig. 2 show, there are apparently (but, as will be shown immediately, not really) two distinct types of initial reaction, one characterized by a rather long, flat maximum and a rapid decrease in the rate of synthesis, and the other by a much shorter maximum with a more gradual rate of decrease. The catalysts which may be considered as being of the long maxi-

num type are pure nickel, nickel-copper, and copper-alumina. Those having short maxima are the precipitated coppers, fused copper, and copper-nickel. In this respect, as in others to be mentioned later, there is no specific "mixture" effect in the copper-nickel series. In general the properties varied gradually from pure copper to pure nickel.

That there is no essential difference between the two types of curves is shown by an examination of the results at different temperatures. In the case of each catalyst there is evidence of a transition, with increasing temperature, from the short maximum to the long continued maximum type, and this evi-

FIG. 2
Rates of water formation in typical runs

dence is conclusive in two instances. Thus when precipitated copper, catalyst No. 1a, which gave curves of the short maximum type at temperatures from 78° to 156°, was run at 164°, it gave a maximum of 9.9 mg. of water per 5 minutes lasting more than four hours, and then showed a rather rapid decrease to 7.0 mg. at the final steady state. Also in the case of copper-alumina, No. 2b, at 94° the curve (shown in Fig. 2) is evidently intermediate in character, since the flat maximum at 6.8 mg. lasts less than half an hour. At a lower temperature, 79°, there was a sharp maximum, and at a higher temperature, 107°, the rate of water formation increased slowly from 9.2 mg. per 5 min. at the end of the first hour to 9.8 mg. at the end of 15 hours. A similar increase in the rate of synthesis during the initial stage was observed for the other catalysts of this type, altho to a lesser degree.

In all cases in which there was a continued maximum, the oxygen leakage was zero up to the point at which the decrease in efficiency took place. Simultaneously with the beginning of this decrease, the oxygen leakage increased to a point such that the sum of the synthesis and leakage accounted for all the oxygen entering the catalyst chamber. The rate of further oxide formation is therefore not measureable by difference.

It should be pointed out at this time that it is not strictly correct to say that the efficiency of the catalyst during the initial stage, when there is no oxygen leakage, is anything less than 100 per cent. There are present under these conditions two competing reactions, one forming oxide which remains on the catalyst, and the other forming water. If, for example, one-tenth of the oxygen striking the catalyst is permanently fixed as oxide, only nine-tenths is left for the catalytic reaction. If the catalyst converts this completely to water, it is doing all that can be expected of it and is in the true

FIG. 3
Temperature-efficiency curves for the steady state synthesis

sense 100 per cent. efficient. If leakage begins, however, the catalyst is clearly not converting all available oxygen to water, and to the extent that it fails to do this, its efficiency is less than 100 per cent. It is correct, therefore, to calculate catalytic efficiencies on the basis of the oxygen entering the catalyst chamber only when there is complete conversion of this oxygen to water, or when there is leakage of oxygen gas thru the catalyst bed.

In a study of the mechanism of a catalytic reaction, it is the steady state conditions which are of most importance. The curves in Fig. 3 show the change in efficiency with temperature for the catalysts in this final steady state. The points plotted are taken from the results of "continuous" runs lasting many days, during which time the temperature of the catalyst was varied back and forth several times over the range indicated. As already

mentioned, continued use of the catalysts resulted in a decreased volume, and this was in general accompanied by a decrease in the catalytic efficiency and the amount of oxide formed in a given time. Successive runs, however, gave closely reproducible results, and the deterioration of the catalysts tended to approach a limiting value, both as regards efficiency and oxide formation. The points shown in Fig. 3 were obtained late in the series of runs with any one catalyst, and represent therefore the efficiencies of the catalysts near this limiting state.

Those points plotted as 100 per cent. efficiency are, in a way, fortuitous. The catalyst in its oxidized condition was heated to successively higher temperatures until the oxide "broke," i.e., reduction of the stable oxide took place. Since heating was effected by means of vapor baths, there was necessarily a discontinuity in going from one temperature to another. In the cases of catalysts Nos. 1a and 1c, reduction of the oxide started immediately and rapidly at the higher temperature. With the other catalysts, reduction progressed much more slowly and in some cases did not start until some time after the higher temperature was reached. The results obtained with fused copper, N. 3, may be given as an example. At 117° the efficiency was 37 per cent. When the temperature was raised to 131° , the efficiency increased immediately to 82 per cent. During the next 14 hours, there was a slow increase in efficiency to 99 per cent. and visible reduction of the oxide started at the top of the catalyst bed where the concentration of free oxygen was least. During the next 24 hours, the efficiency was 100 per cent., the oxygen leakage remained nil, and reduction progressed very slowly downwards for a distance of one-half centimeter. At no time was the rate of water formation greater than 10 mg. per 5 min., and since there was no leakage of free oxygen, reduction must have taken place at a rate too small for measurement. On lowering the temperature to 117° , the reduced portion of the catalyst was again oxidized. It is believed, therefore, that 131° is, within a small limit of error, the minimum temperature at which the stable oxide formed on this catalyst is reduced under the conditions of the steady state synthesis. In other words, it is the lowest temperature at which the catalyst is 100 per cent. efficient.

Similar points were obtained for catalysts Nos. 1b, 1d, 2a, and 2b, altho in none of these cases was reduction as gradual as in the example just given. It is possible, and perhaps probable, that the minimum temperatures of reduction for these catalysts are slightly lower than the points obtained, but these latter can not be greatly in error since the extrapolated curves pass smoothly thru them.

The catalysts in order of decreasing efficiencies in the final steady state are copper-alumina, fused copper, nickel, nickel-copper, copper-nickel, and pure precipitated copper. There is no mixture effect in the copper-nickel series, each constituent seeming to act independently of the other. At the lower temperatures, the nickel-copper is more active than is pure nickel, but in all other cases there is a gradual change in efficiency from nickel to copper. It is of interest to note that the amounts of shrinkage in the preliminary treat-

ment and reduction parallel exactly the efficiencies in the final steady state. Precipitated copper, which shrank most of all, is by far the poorest catalyst, while copper-alumina, fused copper, and nickel, which shrank least, are the best catalysts. Of the two precipitated coppers, that having the harder original granule, No. 2a, shrank less and was somewhat more active catalytically.

A comparison of total amounts of oxide formed by the catalysts and their efficiencies shows another parallel relation. The catalysts which are most active catalytically are also those which possess the greatest capacity for forming oxide. The amount of oxide formed by a given catalyst in the final steady state increases slowly with the length of time it is run without reduction, and there is an accompanying slow decrease in the efficiency of conversion. On the other hand, a freshly reduced catalyst forms during a given time more oxide and is more efficient than a catalyst which has been used for some time. This difference is most marked in the case of the poorer catalysts, and is but slightly evident in the case of a catalyst such as copper-alumina. Undoubtedly this behavior is related to the gradual shrinkage of the catalyst in use and the accompanying change in the physical nature of the surface. That the amount of oxide present is not directly related to the catalytic efficiency is shown clearly by the following data. Catalyst 2b, copper-alumina, was 90 per cent. efficient with 92.2 mg. water-equivalent of oxide present, and in a subsequent run at the same temperature gave a conversion of 84 per cent. with only 42.6 mg. water-equivalent of oxide on its surface. Catalyst 1b, copper-nickel, gave at different times identical conversions of 29 per cent. with 48.2 mg. and 25.0 mg. water-equivalent of oxide present respectively. It can be said in general that a catalyst which is active catalytically is also active in forming oxide, but there is no evidence that the former is a result of the latter.

Because of the tendency to continue the formation of oxide for long periods of time, it was difficult to obtain quantitative data on the relative "saturation" values for oxide formation by the different catalysts. The data are further complicated by the differences in temperatures at which the catalysts were run, and the resulting changes in their rates of oxide formation. The following figures, obtained from runs lasting many hours, are given, therefore, not as absolute, but with the idea of showing relative values for the different catalysts. The figures represent water-equivalents of oxide expressed as milligrams of water per gram of reduced catalyst: copper-alumina, 100; copper-nickel, 30; nickel-copper 27; nickel, 13; fused copper, 12; precipitated copper, No. 2a, 4; and precipitated copper, No. 1a, 2.5. Due to the great difference in density of the precipitated catalysts as compared with the fused copper, a comparison of relative oxide formation based on unit weights has little significance in the latter case. A better comparison is that of total amounts of oxide formed by the three catalysts: copper-alumina, fused copper, and copper-nickel. The volumes of these catalysts were each about 2 cc., and the amounts of oxide were 197 mg. water-equivalent for the copper-alumina, 74 mg. for the fused copper, and 48 mg. for the copper-nickel. The catalysts in

order of decreasing capacities for forming oxide are, therefore, copper-alumina, fused copper, copper-nickel, nickel-copper, nickel, and precipitated copper.

It is evident that there is here a distinct mixture effect in the copper-nickel series. The addition of either metal to the other increases markedly the capacity for forming oxide during the catalytic synthesis of water. Moreover, the copper forms less oxide than does nickel, the mixture containing 88 per cent. copper forms more oxide than the one containing 75 per cent. nickel. This is the only instance of a mixture effect found in this series. That there is not a corresponding effect in the catalytic efficiencies indicates that there is no direct relation between oxide formation and the catalytic mechanism.

The changes in efficiency and oxide forming capacity caused by heating the catalysts to 444° are of interest in connection with changes in the physical structure of the catalysts which took place at this temperature. In all cases there was appreciable shrinkage of the catalysts, a decreased oxide forming capacity, and with but one exception, which was in the case of nickel, an accompanying decrease in catalytic efficiency. The catalyst least affected by the heat treatment was copper-alumina, which shrank only slightly, with no apparent sintering of the separate granules. The efficiency, as determined by six-hour runs immediately before and after the heat treatment, was practically unchanged, but the total amounts of oxide formed during this length of time were 42.6 and 35.6 mg. water-equivalent respectively. The fused copper catalyst shrank about one-eighth and some sintering was evident. The change in efficiency was very great: before heating, a six-hour run gave a maximum of 9.4 mg. water per 5 min. decreasing to 7.5 mg. at the end of the run; after heating, the maximum was 2.4 mg. per 5 min. and the final rate only 1.3 mg. The oxide formed in this time was 13.0 mg. water-equivalent before and 7.4 mg. after the treatment. Precipitated copper shrank to about half its previous volume, and the granules sintered together, holding the shape of the catalyst tube so that considerable jarring was necessary to separate them. Both efficiency and oxide formation decreased more than half. The copper-nickel mixtures suffered a large decrease in both efficiency and oxide forming capacity.

The nickel catalyst shrank nearly 50 per cent. and sintering took place in a manner similar to that described for the precipitated copper. The oxide formation in six-hour runs decreased from 17.2 mg. water-equivalent before heating to 5.0 mg. after; but the catalytic efficiency *increased* from a maximum of 9.4 mg. water per 5 min. lasting 2 hours and a final value of 0.8 mg., to a maximum of 9.8 mg. per 5 min. lasting the full six hour period. Subsequent runs showed a gradual decrease in efficiency and oxide formation, but the efficiency did not, in the entire period of 20 days during which the runs were continued, reach the low value obtained before the heat treatment. Successive runs gave maximum rates of (1) 9.8 mg. water per 5 min. for nearly 6 hours, decreasing to 3.7 mg. at the end of the next hour, and forming 4.2 mg. water-equivalent of oxide; (2) 9.8 mg. per 5 min. lasting 2 hours and falling to 2.1 mg. in six hours, with oxide equivalent to 3.0 mg. water; and (3) 9.8 mg.

water for 1 hour, falling to 1.6 mg. in 6 hours, and forming 3.0 mg. oxide. There is apparent a gradual change toward the previous condition of the catalyst as regards catalytic efficiency but not as regards oxide-forming capacity.

Discussion

The essential likeness of the two apparently different types of initial reaction has been pointed out in the last section. Whether there will be a continued maximum with no oxygen leakage, or a short maximum with leakage starting almost immediately, is apparently dependent on the rates of the two competing reactions which are in evidence during the initial stage of catalysis. If the temperature is sufficiently high, the rate of synthesis will rise to give complete conversion, and there is no reason to expect a decrease in this rate unless the catalyst deteriorates due to a physical change.

At a somewhat lower temperature, where the conversion is not quite complete and the remaining fraction of the oxygen is completely taken up by the metal to form oxide, the duration of the continued maximum will depend on the magnitude of this fraction and on the capacity of the metal for forming oxide. As the temperature is lowered, the duration will decrease owing to the decreased rate of synthesis and the resulting increase in the amount of oxygen available for forming oxide, but there will be a continued maximum as long as the rate of oxide formation and the capacity of the metal are sufficiently great to prevent the escape of free oxygen past the catalyst. When this latter occurs, however, the catalyst surface has become covered with a layer of oxide, and the rate of synthesis will undergo an immediate decrease. On the other hand, when the rates of synthesis and oxide formation are both low, the oxygen leakage starts immediately and a short maximum results. It is evident from the experimental data that the expected transition from the continued maximum at high temperatures to the short maximum at low temperatures takes place at fairly high temperature in the case of copper, but has not been completely attained at 34° in the case of nickel.

Evidence that the formation of oxide and the catalytic process are independent and competing reactions is to be found in the observed increase in the rate of the latter during the initial stage. The catalyst is, as already shown, 100 per cent. efficient during this period when the formation of oxide is progressing thru the catalyst mass; and the formation of water takes place chiefly at, or just beyond, the oxide-metal boundary where the heat effect is greatest. Nevertheless, the oxide covered portion of the catalyst is active to some extent in the synthesis, and since the formation of further oxide on such surface is extremely slow, the amount of water formed on this surface must gradually increase as its length and area increase. With a sufficiently long column of catalyst a limiting state will be reached in which all the oxygen is converted to water on the oxide covered surface, and no free oxygen will be left to extend it farther. This has actually been observed in the case of copper whose oxide is visible. In the case of an insufficient depth of catalyst, however, the oxidation will progress until the whole surface is covered, and at

this point there will be a drop in the rate of water formation except in the marginal case in which the depth of catalyst is just sufficient to effect complete conversion on the oxide covered surface.

The suppression of the oxidation reaction on the oxidized portion of the catalyst thus causes an increase in the rate of synthesis in the first stage and this may reach the point where complete conversion is attained. On the other hand, the covering of the entire catalyst by oxide results in a marked decrease in the rate of synthesis, since such a surface is less active than is one of free metal. In other words, the oxide layer acts as a poison by covering the more active metal surface.

Further evidence for the independence of the catalytic mechanism and the formation of oxide is given by the absence of any mixture effect in the former and its presence in the latter. It seems highly probable that, if the catalytic mechanism involved the stable oxide, an effect which clearly influences the formation of the latter would have a corresponding influence on the catalytic efficiency.

In the final steady state, the formation of further oxide takes place at an extremely slow rate, and this reaction is, therefore, no longer in serious competition with that of catalysis. Since reduction of the stable oxide is inhibited by free oxygen, which is always present when conversion is not complete, it does not seem probable that this oxide is an important factor in the catalytic mechanism. There is another and faster reaction most in evidence during the initial stage, and this undoubtedly continues to play a predominant part in the true catalytic mechanism of the steady state.

The catalyst surface is probably at no time *completely* covered by oxide; copper (or nickel) nuclei are no doubt present at isolated portions of the oxide layer, and it is these nuclei which effect most of the catalytic synthesis. The probable mechanism of the catalysis seems to be activation of an oxygen molecule or atom by its close approach to an active metal atom with the probable formation of an "indefinite" oxide which is readily attacked by hydrogen. It is possible that the hydrogen is activated in a similar way, but the present data do not show whether this is probable or not. Whether an oxide-metal interface is necessary to the synthesis is not definitely shown, but it seems likely that this is not the case. The approach of a single oxygen molecule to an active atom on a free metal surface seems all that is necessary for its activation. At the beginning of the initial stage the whole surface is probably catalytically active, and it is the formation of the stable oxide which decreases this active surface and finally causes the decrease in efficiency.

The relation between hardness of granule, shrinkage, the effect of heating, capacity for forming oxide, and catalytic activity give important information for explaining the catalytic reaction. The experimental results show that those catalysts which undergo greatest shrinkage in the preliminary treatment and reduction are also lowest in catalytic efficiency and oxide forming capacity. Of the two precipitated copper catalysts, the more active was the one having the harder original granule and undergoing the lesser amount of shrinkage. In the series of copper catalysts, the efficiencies paralleled closely

the effects mentioned above. The most efficient of these catalysts was the copper-alumina and this was also most active in forming oxide, suffered least shrinkage, and was least affected by the heat treatment. The fused copper underwent but slight shrinkage and formed large amounts of oxide, but it suffered great injury on heating. The poorest catalysts, the precipitated coppers, shrank largely, formed but little oxide, and were further greatly inactivated by heating.

The behavior of copper-alumina is especially interesting when compared with promoted ammonia catalysts. It has been shown¹ that the promoters used in ammonia catalysts (usually aluminum and potassium oxides) serve to keep the surface of the reduced catalyst relatively large. The function of alumina in the copper-alumina seems to be similar in that it prevents the collapse of the catalyst structure.

These facts are in agreement with the theory of the catalytic surface developed by Professor H. S. Taylor² in several articles. On the basis of this theory, a catalyst like copper-alumina should be very active. Owing to the presence of the aluminum oxide as a supporting network, shrinkage during the preliminary treatment and reduction should be slight, and there should be on the reduced catalyst a relatively large number of copper atoms in an unsaturated condition. For the same reason rearrangement of the copper atoms should be relatively slow, and even high temperature should have no great effect. Pure precipitated copper should, on the other hand, be much more affected in these ways. Reduction should cause shrinkage, and the ready mobility of the unsupported copper atoms should leave a surface with but few exposed edges and corners. The fused copper catalyst shrank only slightly in the preliminary treatment and reduction, but heating to 444° caused a greater change. It seems probable that the oxide remaining in the interior of the granule acted as a support to the atoms of metal on the surface, and that the removal of this oxide resulted in a collapse of the catalyst structure.

A catalyst having active atoms in the sense pictured by the theory should show a parallel relation in the amount of oxide formed and its catalytic activity, and this is borne out by the experimental facts. A similar relationship has been shown for ammonia catalysts by Almquist and Black.³ They find that those catalysts which are most active in the ammonia synthesis are also the ones which form the largest amounts of oxide when exposed to nitrogen-hydrogen mixtures containing small amounts of oxygen or water vapor.

Nickel shrank but little in the preliminary treatment and reduction, and it was much more active than precipitated copper. The original granule was firmer and the mobility of the nickel atom is less than that of copper,—all of which agrees with the theory. The result of heating nickel to 444° is, however, entirely different from that to be expected. There was a decrease in oxide forming capacity in agreement with previous results with other catalysts,

¹ Wyckoff and Crittenden: *J. Am. Chem. Soc.*, **47**, 2866 (1925).

² Taylor: *Proc. Roy. Soc.*, **108A**, 105 (1925); Fourth Report of the Committee on Contact Catalysis, loc. cit.; and others.

³ Almquist and Black: *J. Am. Chem. Soc.*, **48**, 2814 (1926).

but in spite of a large amount of shrinkage and the sintering of the separate granules, the catalytic activity was considerably increased. The present data do not warrant any definite explanation of this phenomenon, but it is extremely interesting to note that nickel behaves abnormally in respect to many of its physical properties when heated above about 360° . There is a change in magnetic properties, in the coefficient of expansion, and in the cooling curve of nickel at this transition temperature. These effects are not permanent, and this is in agreement with the observed tendency of the catalyst to return to its former lower activity.

Benton and Emmett¹ try to show that the stable oxide is an essential step in the catalytic mechanism with nickel. Their results, however, show that if the oxygen is shut off during the final steady state, the rate of reduction of this oxide with pure hydrogen is very much less than the rate of water formation during the synthesis immediately preceding. Since reduction of the oxide is inhibited by the free oxygen present during the synthesis, the rate of water formation should, if the synthesis involves reduction of this oxide, be *increased* by shutting off the oxygen. This was never the case with the catalysts used by Benton and Emmett. Even if the oxygen is shut off during the initial stage, before the oxide has spread entirely over the catalysts surface, the rate of induction is in no way comparable with the rate of synthesis. These authors admit that "unless the rate of reduction *in the catalytic process* is much greater than the rates here observed, successive oxidation and reduction can have only a minor share in the catalytic mechanism." The rates of reduction referred to are for a partially oxidized surface, having therefore a large oxide-metal interface, and are with pure oxygen-free hydrogen. In the steady state, the catalyst surface is covered with oxide, thus giving a much smaller interface between oxide and metal, and appreciable amounts of free oxygen are present. Since reduction of nickel oxide takes place at the interface and is inhibited by free oxygen, it does not seem possible that its rate can be greater under such adverse steady state conditions.

These authors say further, "there is no reason to suppose that the interfacial area between the oxide and the nickel was of the same order of magnitude in the reduction as in the catalytic experiments," and "an 8- or 10-fold increase is all that is necessary to make the observed reduction rates equal to the rates of catalysis." But here they fail to distinguish between the initial stage and the true catalysis of the final steady state. It is hardly conceivable that shutting off the oxygen in the final steady state can *decrease* by 8- or 10-fold the interfacial area, an assumption necessary to explain the observed facts on the basis of their theory. On the contrary, the interface should at first increase in area, since oxygen gas is no longer present to "heal" the break in the oxide film. Therefore, if reduction of the stable oxide accounts for most of the water formed during catalysis, there should be *in all cases* (provided, of course, sufficient oxide is present) a considerable increase in the rate of water formation at the instant of shutting off the oxygen. This is contrary to the observed facts.

¹ Benton and Emmett: J. Am. Chem. Soc., **48**, 632 (1926).

In referring to the interpretation given in our first paper, Benton and Emmett state that it was "not realized (by Larson and Smith) that the reduction of nickel oxide by hydrogen is an autocatalytic process." This is incorrect. Whether or not the reduction is autocatalytic is of little importance unless reduction is free to take place. That it is not free to do this in the presence of gaseous oxygen at the temperatures in question is well established, and it was this consideration that led to our conclusion that the stable oxide "probably contributes little to the total water being formed."

It was found in our earlier work, however, that under certain conditions, shutting off the oxygen in the final steady state caused a considerable and immediate increase in the rate of water formation. Were it not for the known inhibiting action of free oxygen on the reduction, and the evidence of a much faster reaction in the initial and later stages, this would support the theory involving the stable oxide. In view, however, of these factors, as well as of the fact that there is not *in all cases* such an increase, this mechanism does not appear to be a probable one, and the theory presented in the first paper seems to require no modification.

It is necessary to recognize, however, that the most probable mechanism as postulated in that and the present paper, may differ from that of alternate oxidation and reduction merely in degree. The distinction is analogous to that between an isolated molecule or atom of oxygen adsorbed on a clean metal surface, and an extended film of metallic oxide. It is commonly recognized in the latter example that there is no sharp dividing line between the two. It seems important, nevertheless, to distinguish between the stable oxide and a molecule of oxygen which becomes activated by its close approach to an active metal atom. It is no doubt due to its capacity for forming oxide that the catalyst is able to activate an oxygen molecule and render it capable of ready union with hydrogen.

The most probable mechanism for the water synthesis over copper and nickel catalysts appears, then, to be activation of oxygen molecules or atoms with the resulting formation of an "indefinite" oxide, by which they are opened to attack by hydrogen. It seems reasonably certain that the synthesis in the steady state is much more rapid than can be accounted for by reduction of the stable oxide, and for this reason the mechanism postulated by Benton and Emmett appears to play but little part in the true catalytic reaction.

The author wishes to thank Professor William C. Bray for his interest in this problem and the many valuable suggestions he has made, both during the experimental part and in the writing of this paper.

Summary

The following catalysts have been studied in the water synthesis reaction at temperatures between 75° and 180°, and with an oxygen concentration of 2.4 per cent.: copper, nickel, two mixtures of these metals, a mixture of copper and alumina,—all prepared by reduction of the precipitated hydroxides; and a sample of copper prepared by reducing the fused oxide.

The most efficient catalysts in the final steady state synthesis were also those which formed the greatest amounts of oxide during the catalysis, and which underwent least change in physical structure on reduction and later heat treatment. The catalysts in order of decreasing catalytic efficiencies are copper-alumina, copper from fused oxide, nickel, nickel-copper, copper-nickel, and copper from the precipitated hydroxide.

No mixture effect was found in the copper nickel series as regards catalytic efficiency, but one was clearly evident with respect to the amount of oxide formed during catalysis.

Heating the catalysts to 444° for one-half hour caused a decreased efficiency except in the case of nickel. It is suggested that the anomalous behavior of the latter may be related to the existence of a transition point at about 360° which causes changes in the physical properties of the metal.

The importance of the physical nature of the catalyst surface has been emphasized. The experimental results are in agreement with the theory of the catalyst surface developed by Professor H. S. Taylor.

The probable mechanism of the catalysis appears to be interaction of hydrogen molecules and activated oxygen molecules or atoms, probably in the form of an "indefinite" oxide, at points of greatest activity on the catalyst surface. It has been shown that the stable oxide probably plays but little part in the synthesis and that, therefore, the theory postulated by Benton and Emmett involving this oxide, is not supported by the experimental facts. The formation of the stable oxide seems to be an unavoidable side reaction which ultimately results in partial poisoning of the catalyst.

THE APPLICATION OF THE THIRD LAW OF THERMODYNAMICS TO SOME ORGANIC REACTIONS

BY GEORGE S. PARKS AND KENNETH K. KELLEY

Preliminary Discussion

Probably the most satisfactory statement of the proposed third law of thermodynamics is that of Lewis and Gibson¹: "If the entropy of each element in some crystalline form be taken as zero at the absolute zero, the entropy of any pure crystal at the absolute zero is zero, and the entropy of any other substance is greater than zero." The last portion of this statement was prompted partly by theoretical considerations and partly by evidence adduced from the data of Gibson, Parks and Latimer² on the specific heats of ethyl and n-propyl alcohols and their equimolal mixture. From these data it appeared that at 0°K. the entropy of a solution probably exceeds that of the pure components by a small finite value and the entropy of glassy ethyl alcohol may possibly exceed that of the crystals by about 1.08 units per mol. More recently this comparison between the glassy and liquid states has been made in a more convincing fashion in the case of glycerol. In studies upon this substance by Simon³, by Gibson and Giauque⁴, and finally by Simon and Lange⁵ the heat capacity measurements have been carried down to 10.6°K. with the result that the estimated entropy of the glass at 0°K. exceeds that of the crystals by 4.6 (± 0.3) units per mol. New data on the heat capacities of the glass and crystals in the cases of both ethyl⁶ and n-propyl⁷ alcohol point to the same conclusion: namely, that the entropy of a glass at the absolute zero exceeds that of the corresponding crystalline form.

Considerations such as these have led Eastman⁸ to suggest that a pure crystalline substance has a positive, tho probably small, value for its entropy at the absolute zero, if the unit of structure of the crystal contains a large number of atoms. In this respect such a compound would bear a general resemblance to a glass and would differ from it merely in degree. Such compounds with complex cell units and finite positive entropies at 0°K. would probably be found largely in the field of organic chemistry. However, more recently Paulding and Tolman⁹, applying the methods of statistical mechanics, have deduced the conclusion that "the entropy of a perfect crystal

at the absolute zero is not dependent on the complexity of the unit of crystal structure", in distinct contradiction to this suggestion by Eastman.

From a practical standpoint the first portion of the preceding statement of the third law of thermodynamics, that providing for zero entropy for a pure crystalline substance at the absolute zero, is of such importance to physical chemistry that it should be thoroly tested experimentally. This may be done in the case of a given reaction at a definite temperature by comparing the entropy change, ΔS , calculated from heat capacity data on the assumption of the third law with the corresponding value for ΔS calculated indirectly from the free energy change (ΔF) and the change in heat content (ΔH) by means of the fundamental relationship,

$$\Delta F = \Delta H - T\Delta S. \quad (1)$$

Such a comparison, in order that it may have any real significance, requires very accurate data; since several types of experimentally measurable quantities are involved and even moderate errors in these, if cumulative, may produce astonishing discrepancies. For inorganic reactions involving pure crystalline substances a considerable number of these tests have been made and in general it has been found that the more reliable the data obtainable the better is the agreement with the requirements of the third law. Thus, for instance, Lewis and Gibson¹ in 1917, reviewing the data for nine such tests, found an average discrepancy of 1.6 entropy units; while a few years later Lewis, Gibson and Latimer², using the extremely accurate electromotive force measurements of Gerke, found in the case of three of these reactions involving chlorides that the average apparent deviation from the third law had been reduced tenfold. Hence, insofar as simple, crystalline, inorganic compounds are concerned, the third law as stated at the beginning of this paper seems to have been placed on a very firm basis.

In the field of organic chemistry the situation is quite different. Organic compounds in general do not lend themselves to simple, reversible reactions involving the elements and suitable for the measurement of equilibria. Still fewer of them are involved in such reactions as may be studied by electromotive force measurements with a reversible galvanic cell. Hence, the third law of thermodynamics, if valid, serves as a very valuable tool for the calculation of the free energies of organic substances by the sole use of thermal data, such as heats of combustion and low temperature heat capacity values. We say "if valid" because it is precisely in the field of organic compounds that the tests of the third law have been fewest and least satisfactory. In 1923, when the present investigation was undertaken, the only earlier work on this question was that of Gibson, Latimer and Parks³ dealing with the following three reactions:

¹ Lewis and Gibson: J. Am. Chem. Soc., 39, 2580 (1917).

² Lewis, Gibson and Latimer: J. Am. Chem. Soc., 44, 1014 (1922).

³ Gibson, Latimer and Parks: J. Am. Chem. Soc., 42, 1533 (1920).

For the purposes of the moment we have now revised and corrected their data in the light of the later information given by Lewis and Randall¹. The final results are summarized in Table I. In the case of the first two reactions the values for ΔF°_{298} calculated by Lewis and Randall have been corrected by means of vapor pressure data recently obtained for formic acid by Ramsperger and Porter². The ΔS_{298} values found by Equation 1 appear in the fourth column of the table. The corresponding values (Column 5) calculated on the assumption of the third law have been obtained by use of the latest table for the entropies of the elements.³ In all cases we have attempted to estimate the maximum errors in these ΔS figures.

TABLE I
Summarized Data for Earlier Tests of the Third Law

Reaction	ΔF°_{298} cal.	ΔH_{298} cal.	ΔS_{298} , by equation 1 cal./degree	cal./degree by third law
I	+ 4,100	- 5,200	- 31.2 (± 6)	- 28.4 (± 4)
II	- 85,000	- 99,700	- 49.3 (± 7)	- 44.5 (± 4)
III	- 47,280	- 78,800	- 105.7 (± 8)	- 88.7 (± 10)

A comparison of the ΔS results obtained by the two different methods shows that in the case of all three reactions the agreement is within the limits of maximum error in the quantities involved. However, these possible errors are very large and from the data just given we are only justified in concluding that the third law is roughly valid for organic reactions. This situation, in view of the increasing tendency to assume the exact validity of the third law in the case of organic reactions, calls for further and, if possible, more accurate tests. The present study has been undertaken to partially fill the need.

Perhaps, before proceeding further, it will be well to analyze the problem so that we may see wherein the uncertainties in the ΔS values are apt to arise. ΔS calculated by Equation 1 obviously depends upon the accuracy of the values for ΔF and ΔH . Now ΔF in these tests is ordinarily the result of equilibria measurements and in some cases can be determined with a fairly high degree of accuracy, especially if only one reaction is involved and the temperatures concerned are close to that of the room. If on the other hand, as in reactions II and III, the value for ΔF is the result obtained by the addition of several equations and their corresponding ΔF quantities, the errors may be cumulative and the uncertainty in the final value will mount with surprising rapidity. Thus, in reaction II a possible error of 210 calories in the free energy of formation of CO^4 alone contributes thereby an uncertainty of 0.7 entropy unit in the final result. Equally important are errors in the ΔH values. In some reactions the change in heat content, ΔH , may

³ Lewis, Gibson and Latimer: J. Am. Chem. Soc., **44**, 1016 (1922).

⁴ Eastman and Evans: J. Am. Chem. Soc., **46**, 902 (1924).

be obtained directly by a calorimetric method or indirectly from measurements of the e.m.f. of a galvanic cell or of equilibria over a range of temperatures. These indirect methods are frequently of greater accuracy than the calorimetric. Especially is this likely to be true in the case of organic reactions in which heats of combustion are used, because most of the combustion data now available is from early work and may involve errors of one per cent or more. Thus, in the case of reactions I and II an error of 600 calories (1%) in the heat of combustion of formic acid produces an equal error in the ΔH values and an error of 2.0 units in the entropy change in Column 4. On the other hand, considering the ΔS values calculated by the third law, we find that they are probably good to about one or two per cent when entirely dependent on accurate specific heat data. However, in cases such as the entropies of formic acid and urea the experimental data did not go below liquid air temperatures and it was necessary to use the "n formula" of Lewis and Gibson¹ for extrapolation to 0°K. This relationship when applied to organic compounds constitutes, we believe, only a first approximation and may involve errors of even 25% in estimating the entropies below 90°K. Thus, for instance, we estimate that the entropy of formic acid, obtained by this formula, may possibly be in error by 3.0 units.

In view of all these considerations, the reaction which we in 1923 selected for again testing the third law was the following:

Sabatier² had shown that this reaction in the gaseous phase was reversible and later Rideal³ had measured the equilibria involved over a range of temperatures by means of a static method. His results, however, were rather uncertain, owing to the great possibility of side reactions with such a procedure. We in the present study have employed a dynamic method and have obtained the equilibrium constant at several temperatures. From this series of equilibrium constants we have finally obtained ΔF°_{298} and ΔH_{298} for the above reaction. We have also measured the heat capacities of iso-propyl alcohol and acetone from 70° up to 298°K. and in this way we have been able to calculate the corresponding entropies at 298° on the assumption of the third law. Of course, in estimating the entropy increases for these compounds from 0° to 70°K. we have been forced to employ some extrapolation method and so have had recourse to the afore-mentioned formula of Lewis and Gibson. However, as we are later concerned with the difference between the entropies of these two compounds in obtaining ΔS_{298} , any error arising from use of the "n formula" is minimized in this case and is probably not greater than 1.0 entropy unit. The entropy of a mol of hydrogen at 298°K. is also involved but this is probably known with considerable accuracy; in fact, Lewis, Gibson and Latimer consider their figure to be good to better

¹ Lewis and Gibson: *J. Am. Chem. Soc.*, **39**, 2565 (1917).

³ Rideal: *Proc. Roy Soc.*, **99A**, 153 (1921).

than one-tenth of a unit. All in all, then, this organic reaction serves as a very promising test of the third law¹.

Within the last few years sufficient data have accumulated in the literature to provide for another very good test in the case of the reaction:

This chemical change is very similar in principle to the preceding one. Therefore, we shall briefly consider it after first presenting our data for the iso-propyl alcohol, acetone reaction.

Experimental

The experimental work owing to the nature of the problem resolved itself into two distinct parts, which here will be considered separately.

Materials. During the course of the investigation several samples of iso-propyl alcohol were prepared and used. In our purification process "refined" iso-propyl alcohol was first dehydrated by two successive distillations over lime in the ordinary manner. In each instance the resulting product was carefully fractionated and the middle portion, about 60% of the total, was selected for the measurements. The average density of these middle portions was 0.78093 at 25°/4°, which corresponds to 99.96% alcohol on the basis of the criteria² previously employed.

Pure, absolute acetone, obtained from the National Aniline and Chemical Company, was used without further purification for the heat capacity determinations of Part I. For the equilibrium measurements of Part II the ordinary C.P. acetone of commerce was purified by treatment with anhydrous calcium chloride as in the work of Parks and Chaffee.³ After the final fractionation process, the middle portion representing about one-half of the total was selected for use. It distilled between 56.1° and 56.2°C. and had a density of 0.7855 at 25°/4°.

Part I: Heat Capacity Data

In principle, the method of Nernst was employed with an aneroid calorimeter in determining the "true" specific heats and the fusion data. A measured amount of heat was supplied by an electric current to the substance

¹ In connection with this test of the third law there is one point which should be noted. If the entropy of hydrogen at 0° K be taken as zero, then according to Eastman's argument it is conceivable that the two compounds in question, iso-propyl alcohol and acetone, may have small positive entropies, possibly of the order of two or three tenths of a unit, at the absolute zero. Furthermore, if this be true, these values will more or less cancel one another in the subsequent calculation of ΔS_{298} and the result will not differ appreciably from that obtainable on the basis of zero entropies at 0° K. Hence, our present test cannot be used to either prove or disprove Eastman's speculations, as the possible experimental error in our ΔS_{298} value obtained from the heat capacity data is at least 1.0 entropy unit or, perhaps, five times the magnitude of any such hypothetical effect. However, Eastman's argument is really of theoretical rather than of practical interest insofar as the simpler organic compounds are concerned, and in the present paper we are primarily involved with the question of the applicability of the third law as a fairly accurate, useful tool for the calculation of free energies. Certainly for such a practical purpose the above reaction serves very well for testing the (at least approximate) validity of the third law in the field of organic chemistry.

contained in a copper calorimeter, which was suspended in a vacuum and surrounded by a silvered copper cylinder in order to diminish the conduction and radiation of heat to and from the surroundings. A thermocouple in the center of the calorimeter measured the rise in temperature. The entire apparatus and details of experimental procedure have been fully described in other places.¹ In view of the accuracy of the various measurements involved,

the absolute error in the experimental values is probably less than 1%. Thus in the case of iso-propyl alcohol two samples were studied with different thermocouple thermometers, lead-wire connections, etc. The results of the two sets of determinations, made over a year apart, agreed to 0.5% or better and served to indicate the reproducibility of the values obtained.

The specific heats and the fusion data, expressed in terms of the 15° calorie and with all weights reduced to a vacuum basis, appear in Tables II-IV.

Part II: The Equilibrium Measurements

*Method.*¹ As stated before, a dynamic method was used in studying the equilibrium between iso-propyl alcohol, acetone and hydrogen in the gaseous phase. Briefly it was as follows. Pure electrolytic hydrogen, stored in a cylinder, was passed slowly thru two drying towers containing phosphorus pentoxide and then into an empty condensing tube immersed in liquid air, a precautionary device to extract impurities such as carbon dioxide or hydrocarbons; however, none of these were found. From here the hydrogen passed thru two bubblers, each containing 25 to 40 cc of iso-propyl alcohol or acetone or of a mixture of the two, depending on the direction from which the equilibrium point was being approached. These bubblers were kept at the temperature of the melting point of ice when the iso-propyl alcohol or a mixture was used and at the boiling point of liquid ammonia when filled with acetone. There were two reasons for this: first, it was desirable to have the concentrations of the iso-propyl alcohol and acetone low so that the partial pressures would follow the perfect gas law; and second, it was found by experiment that equilibrium could not be obtained with a convenient rate of gas flow if the concentrations were high. These bubblers sufficed to saturate the hydrogen with the vapor of the liquid. After saturation the gas passed into the reaction tube which will be described subsequently. Here in the presence of the catalyst the reaction took place and the resulting gaseous mixture then passed into a condensing tube immersed in liquid air, which solidified the iso-propyl alcohol and acetone. After a 1 or 2 cc sample of these had been formed by condensation (a process which took six to twelve hours), it was removed and analyzed by the refractometer method previously used by Parks and

¹ The method and results of this investigation of the equilibrium between iso-propyl alcohol, acetone and hydrogen were reported by one of us (K.K.K.) in a paper read before the chemical section meeting of the Pacific division of the American Association for the Advancement of Science at Mills College, California, June 18, 1926.

Chaffee.¹ This method involved simply the determination of the index of refraction of the sample by a Zeiss-Pulfrich refractometer. The resulting value, when referred to a chart on which we had plotted the refractive indices for known mixtures of acetone and iso-propyl alcohol against the corresponding molal compositions, gave the molal composition of the condensate sample to within 0.6%. As this analytical procedure was easy and rapid and required less than 1 cc of liquid, it was ideal for our purposes.

The Reaction Tube. The reaction tube consisted of a Pyrex U-tube about 90 cm. long and 1.2 cm. in diameter. The side thru which the reactants entered was almost completely filled with catalyst, while that thru which the products passed out was one-third full; by this arrangement the emerging gases were well removed from the catalyst before any temperature change was encountered. The reaction tube was suspended in a long Monel metal can which served as a container for the vapor bath and the boiling liquid in equilibrium therewith. This cylindrical can was wound with a heating coil and covered with sheet asbestos and a 2.5 cm. layer of "85% magnesia" insulation. The bath liquid was heated partly electrically and partly by a micro burner. The temperature of the vapor around the reaction tube was measured with a single element copper-constantan thermocouple and a White potentiometer.

Finely divided copper was used as a catalyst, since Sabatier had found that it did not appreciably catalyze side reactions such as dehydration. This catalytic copper was prepared partly from cuprous oxide and partly from copper gauze by repeated oxidations and reductions. The first reductions were made with hydrogen and the last with iso-propyl alcohol. Air was used as the oxidizer. These repeated oxidations and reductions, about twenty in number, were made at progressively decreasing temperatures, the final one being at about 100°C. This process gave a catalyst which proved to be sensitive and made it possible to obtain the equilibrium mixture of gases from either the iso-propyl alcohol or the acetone side, altho at the lower temperatures the equilibrium point lies well over toward the alcohol side and more consistent results were always obtainable by starting from this direction.

The Equilibrium Constants. The equilibrium measurements were made by use of aniline, naphthalene and ethylene glycol as bath liquids. Of these substances the first two were very satisfactory; the ethylene glycol, however, decomposed more or less on prolonged heating with a resulting rise of the boiling point. Above 190°C. the gas entering the reaction tube consisted of either hydrogen and pure iso-propyl alcohol or of hydrogen and pure acetone. At the temperature of boiling aniline (184.3°C.), on the other hand, it was not possible to obtain equilibrium by using hydrogen and pure acetone, so a mixture of mol fraction 0.11 acetone to 0.89 iso-propyl alcohol was placed in the saturation bubblers when approaching equilibrium from the acetone side.

¹ Parks and Chaffee: J. Phys. Chem., 31, 442 (1927).

In the vapor of this mixture at 0°C. acetone was present at least to the extent of 50 mol per cent as indicated by the results of Parks and Chaffee. When equilibrium was approached from the alcohol side, hydrogen and pure iso-propyl alcohol were used as at the higher temperatures.

Under our experimental conditions all the gases involved approximate to the perfect gas behavior and their fugacities are equal to the corresponding partial pressures. Hence, the equilibrium constant for the reaction

is given by the equation, $K = P_2P_3/P_1$ where P_2/P_1 is the ratio of the partial pressures of acetone and iso-propyl alcohol and P_3 is the partial pressure of hydrogen, measured in atmospheres. The ratio, P_2/P_1 , is equal to the molal ratio of acetone to iso-propyl alcohol in the condensate and was evaluated by the refractometer analysis. The partial pressure of hydrogen was found by subtracting from the total pressure (barometric) the vapor pressure of the liquid employed in the saturation bubblers before the reaction tube, as the change in composition due to the reaction does not affect the third significant figure of the hydrogen pressure obtained in this manner. Our results appear in Tables V-IX. In all cases the prefix "a" before the number of a determination indicates that equilibrium was approached from the alcohol side and the prefix "b" that it was approached from the acetone side.

Calculations and Discussion

ΔS_{298} by the Third Law. According to the statement of the third law of thermodynamics at the beginning of this paper, the entropies of the pure crystalline acetone and iso-propyl alcohol are zero at the absolute zero. Then the entropy of each compound in the liquid state at 298° K. (i.e. 25° C.) is given by the equation,

$$S_{298} = \int_0^{298} \frac{dQ}{T} \quad (2)$$

For convenience in the calculations this may be expanded as follows,

$$S_{298} = \int_0^{70} \frac{C_P \text{ (crystals)}}{T} dT + \int_{70}^{T'} \frac{C_P \text{ (crystals)}}{T} dt + \frac{\Delta H \text{ (fusion)}}{T'} + \int_{T'}^{298} \frac{C_P \text{ (liquid)}}{T} dT \quad (3),$$

where T' is the melting point. The first integral in this expression,

$$\int_0^{70} \frac{C_P \text{ (crystals)}}{T} dT,$$

cannot be evaluated directly from the experimental data and therefore the "n formula" of Lewis and Gibson has been utilized for the extrapolation. By application of their methods to the data for iso-propyl alcohol, the values $n = 0.357$ and $S_{70} = 10.41$ cal./degree have been obtained. This entropy result is undoubtedly too high and possibly the absolute error in it is two or three units. However, for the purposes of a comparative study of the entropies of iso-propyl alcohol and acetone the value will be retained as given above, since without doubt the application of the Lewis-Gibson extrapolation method to this alcohol and to acetone involves comparable errors which will be largely eliminated in obtaining ΔS , the entropy increase in the reaction.

The remaining three terms on the right-hand side of Equation 3 can be evaluated with much greater certainty. The quantity ΔH (fusion)/ T' is obtainable directly from the experimental data of Table IV. The two integrals were determined graphically by plotting the values of C_P per mol as ordinates against $\ln T$ as abscissas and measuring the area under the curve. The results for both substances appear in Table X.

TABLE X
Entropy Data

Substance	Crystals		Entropies per mol		S_{298}
	0-70°	Above 70°	Fusion	Liquid	
Iso-Propyl Alcohol	10.41	14.57	6.86	14.28	46.1
Acetone	14.35	15.90	7.65	14.76	52.7

The entropy of a mol of hydrogen is 29.4 units at 298° K. according to Lewis, Gibson and Latimer. Therefore, for the reaction $(\text{CH}_3)_2\text{CHOH}$, liquid = $(\text{CH}_3)_2\text{CO}$, liquid + H_2 , gas, $\Delta S_{298} = 52.7 + 29.4 - 46.1 = 36.0$ cal./degree on the assumption of the third law. The error in this value for ΔS is probably less than 1.5 entropy units.

ΔS_{298} from the Equilibrium Data. We shall now consider the equilibria data and compare the value for ΔS_{298} thereby obtained with the preceding one.

The rate of change of ΔH (i.e. the heat absorbed) with respect to the temperature for any reaction is given by the equation,

$$\left(\frac{\delta \Delta H}{\delta T}\right)_P = \Delta C_P \quad (4),$$

where ΔC_P in the present case is the heat capacity of one mol of gaseous acetone plus that of one mol of hydrogen minus the heat capacity of one mol of gaseous iso-propyl alcohol, since here we must consider the reaction in the gaseous phase as in the equilibria measurements. The equations for the heat capacities of acetone and iso-propyl alcohol as functions of the temperature are not known. That for hydrogen, calculated from values given by Partington and Shilling,¹ is per mol $C_P = 6.65 + 0.00070 T$. Altho the heat capacity of iso-propyl alcohol is probably somewhat larger than that for acetone, it seems reasonable on the basis of existing data for various substances to believe that the difference is not great. Therefore, in the present

¹ Partington and Shilling: "Specific Heats of Gases," p. 206 (1924).

reaction we shall take ΔC_P as equal to 4.0 calories. This procedure is admittedly somewhat arbitrary. However, it does not greatly affect our calculations of ΔS or our conclusions, as any error in ΔC_P causes practically compensating errors¹ in ΔF and ΔH . Integrating Equation 4 on this assumption for ΔC_P , we obtain the expression

$$\Delta H_T = \Delta H_0 + 4.0 T \quad (5),$$

where ΔH_0 is the constant of integration.

For the free energy change in a reaction, the following general relation exists,

$$\left[\frac{\delta(\Delta F/T)}{\delta T} \right]_P = \frac{-\Delta H}{T^2} \quad (6).$$

Substituting the value for ΔH given by Equation 5, integrating and then multiplying thru by T , we obtain the expression

$$\Delta F_T = \Delta H_0 - 4.0 T \ln T + I T \quad (7)$$

where I is the constant of integration.

The constants, ΔH_0 and I , can be evaluated by use of two values for ΔF_T obtained at different temperatures. These in the present case can be calculated from the measured equilibrium constants at the respective temperatures of boiling aniline and boiling naphthalene by means of the equation

$$\Delta F_T = -R T \ln K. \quad (8)$$

The essential data are:

$$K = 0.36 \text{ at } 184.3^\circ \text{ C. or } 457.4^\circ \text{ K.; } \Delta F = 933 \text{ cal.}$$

$$K = 1.15 \text{ at } 218.0^\circ \text{ C. or } 491.1^\circ \text{ K.; } \Delta F = -137 \text{ cal.}$$

Substituting these values of ΔF in Equation 7 and solving the two simultaneous equations, we obtain $I = -2.6$ and $\Delta H_0 = 13,310$ cal. Therefore Equations 5 and 7 become

$$\Delta H_T = 13,310 + 4.0 T \quad (9) \text{ and}$$

$$\Delta F_T = 13,310 - 9.21 T \log T - 2.6 T, \quad (10)$$

from which the changes in heat content and free energy for the reaction may be obtained at any temperature. As a check upon the validity of these equations we have also used the equilibrium constants obtained for the ethylene glycol temperatures to calculate the corresponding free energy changes (ΔF), which then afford us alternate values for I when substituted in Equation 10. For a complete consideration of the problem we have treated Rideal's data obtained by his static method in the same way. All these results appear in Table XI.

¹ Thus, for instance, we have also carried out all our calculations on the assumption that $\Delta C_P = 6.0$ cal. (an improbably high value, we believe), with the result that our final entropy change becomes 34.9, instead of 35.9 as shown subsequently.

TABLE XI
Equilibria Data and the Constant I

	T	K	ΔF_T	I
Parks and Kelley	457.4	0.36	+933 cal.	-2.6
	491.1	1.15	-137 "	
	469.5	0.533	+587	-2.5
	473.2	0.648	+407	-2.7
	474.9	0.667	+383	-2.5
Rideal	378.1	0.00028	+4,410	+0.2
	423.1	0.0204	+3,270	+0.5
	448.1	0.177	+1,540	-1.8
	473.1	0.523	+610	-2.3
	498.1	1.35	-300	-2.4
	523.1	4.82	-1,640	-3.5
	548.1	12.0	-2,710	-4.0

Examination of the values for I shows that our data obtained by the dynamic method are very concordant and that Rideal's data over the temperature range 448°-523° K. inclusive are in fair agreement with our own. However, this is not true for his two lowest temperatures, and his result for the highest temperature is also indicative of an increasing departure from -2.6, our mean value. We believe that the correct explanation for this situation is to be found in a failure to obtain equilibrium at the lower temperatures and to secondary decomposition of the acetone at the higher temperatures. To quote his own words, "it was found in general that slight decomposition could not be avoided and that, although the decomposition curves could be repeated, the values obtained for the process of hydrogenation were by no means regular. If sufficient time were given for the system to arrive at equilibrium, secondary decomposition occurred relatively rapidly at high temperatures, and after two or three hours contact at low temperatures."

Therefore, using Equations 9 and 10, we calculate for the reaction at 298° K. and 1 atmosphere pressure,

However, it is customary to take the liquid state as the standard state of iso-propyl alcohol and acetone, since that is the ordinary form for these substances at 298° K. and 1 atmosphere pressure. Now for the process,

$\Delta H_{298} = 10,620 - 300 = 10,320 \text{ cal.},$ where 10,620 cal. is the heat of vaporization¹ of iso-propyl alcohol at 25°C under its own vapor pressure, 44.0 mm. of mercury, and -300 cal. is our estimate of the Joule-Thomson effect for compressing the resulting vapor isothermally from 44 to 760 mm.; and $\Delta F_{298} = R T \ln 760/44 = 1690 \text{ cal.}$

¹ Parks and Barton: J. Am. Chem. Soc., 52, 26 (1928).

In like manner for the process,

(c) $(\text{CH}_3)_2\text{CO}$, gas at 1 atm. = $(\text{CH}_3)_2\text{CO}$, liquid at 1 atm.,

$\Delta H_{298} = -7590 + 200 = -7390$ cal., where 7,590 cal. is the heat of vaporization¹ of acetone at 25°C under its own vapor pressure, 226.5 mm.,² and + 200 cal. is our estimate of the Joule-Thomson effect for expanding the vapor isothermally from 760 to 226.5 mm.; and $\Delta F_{298} = R T \ln 226.5/760 = -720$ cal.

Finally, combining Equations a, b and c, we obtain for the standard state reaction,

$\Delta H_{298} = 17,430$ cal.; and $\Delta F_{298}^\circ = 6,720$ cal. For the entropy change, these results give by Equation 1: $\Delta S_{298} = 35.9$ cal./degree. This value for ΔS_{298} is probably good to within 2.0 entropy units and is in excellent agreement with the result, $\Delta S_{298} = 36.0 (+1.5)$, obtained by means of the third law. While the check in the present instance is undoubtedly somewhat fortuitous, it seems reasonable to claim that this is a much better test of the third law in the case of an organic reaction than any heretofore proposed.

The Hydroquinone, Quinone Reaction

As mentioned before, the reaction,

provides us with another test of the third law.

Lange³ has determined the heat capacity of crystalline hydroquinone and quinone from liquid hydrogen temperatures up to that of the room. Without doubt his results are reasonably accurate and will serve excellently for estimating the respective entropies of these two substances at 285°K. (i.e. 12°C) on the assumption of zero entropy at zero absolute. Thus, by plotting his values for the molal heat capacity of hydroquinone against the natural logarithms of the corresponding temperatures, we obtain by graphical integration 31.3 units for the increase in entropy between 20° and 285°K. There are no heat capacity data for this substance below 20° but the work of Simon⁴ has indicated that the Debye T^3 law holds for organic substances up to about 12°K and that above this point the heat capacity changes gradually so as to become at first proportional to the square of the temperature and finally, in the neighborhood of liquid air temperatures, directly proportional to the temperature. With this information we have estimated the entropy increase for hydroquinone between 0° and 20°K to be 0.8 unit per mol. Then, on the assumption of the third law, the total entropy at 285°K is 32.1 units per mol.

¹ Felsing and Durban: J. Am. Chem. Soc., **48**, 2893 (1926).

² Parks and Chaffee: J. Phys. Chem., **31**, 442 (1927).

³ Lange: Z. physik. Chem., **110**, 350 (1924).

⁴ Simon: Ann. Physik, (4) **68**, 260 (1922); Z. Physik, **38**, 227 (1926).

In similar fashion we have estimated the entropy increase for quinone to be 1.4 cal./degree in going from 0° to 20°K. From 20° to 285°K the increase, obtained by graphical integration, amounts to 36.4 units per mol. Thus the total entropy at 285°K is 37.8 cal./degree.

As stated before, the entropy of a mol of hydrogen at 298°K is 29.4 units. C_p for hydrogen at room temperature is 6.85 cal. and hence $S_{285} = 29.4 - 6.85 \ln 298/285 = 29.1$ cal./degree. By the third law we then find for the above reaction, $\Delta S_{285} = 37.8 + 29.1 - 32.1 = 34.8 (\pm 1.0)$ cal./degree.

The electromotive force, E , and its rate of change with temperature, dE/dT , have been determined by Conant¹ and by Schreiner² for a galvanic cell involving this particular reaction. These results have not been obtained directly but represent indirect determinations from a study of the quinone-quinhydrone and the quinhydrone-hydroquinone electrodes. However, in all probability these values are very reliable, as the cells employed were reversible and reproducible. Conant obtained 0.690 volts for the e.m.f. associated with the reaction under consideration and 0.00072 for dE/dT at 285.6°K. Similarly Schreiner found $E = 0.6905$ and $dE/dT = 0.000770$ at 285°. The two values for E are in excellent agreement, altho unfortunately the respective results for the temperature coefficient differ by over 6%.

ΔS for a reaction is related to dE/dT by the simple equation

$$\Delta S = 23,074 \left[\frac{\delta E}{\delta T} \right]_p. \quad (11)$$

Hence, for this reaction $\Delta S_{285} = 33.2$ according to Conant's data and 35.5 cal./degree according to the data of Schreiner. The mean of these two results, 34.4, is probably accurate to within 2.0 units and is in excellent agreement with the value previously obtained from the heat capacity data on the assumption of the third law of thermodynamics. Thus we have here another very good check on the third law in the case of an organic reaction.

Summary

1. The present status of the proposed third law of thermodynamics has been reviewed with special reference to its applicability to organic reactions. In this connection it has been pointed out that none of the earlier tests of this principle in the field of organic chemistry may be considered adequate.

2. In view of this situation, we decided in 1923 to again test the third law, using the reaction,

Accordingly, we have measured the heat capacities of iso-propyl alcohol and acetone in the crystalline and liquid states from 70° to 298°K. We have also determined the heat of fusion of each substance at its melting point. From these thermal data ΔS_{298} has been calculated on the assumption of the third law.

¹ Conant and Fieser: J. Am. Chem. Soc., 45, 2198 (1923).

² Schreiner: Z. physik. Chem., 117, 77 (1925).

The equilibrium constants for this reaction in the gaseous phase have been measured with copper as a catalyst over the temperature range, 184° – 218°C . With the aid of these results we have calculated ΔF_{298} and ΔH_{298} for the reaction involving liquid iso-propyl alcohol and acetone. The value for ΔS_{298} thereby obtained is in good agreement with that calculated from the thermal data. This check indicates the validity of the third law in the field of organic chemistry.

3. Recent data pertaining to another organic reaction,

have been utilized in obtaining a second very accurate test of the third law.

THE OPTICAL SENSITIZING OF SILVER HALIDE EMULSIONS

Part I. The Adsorption of Orthochrome T to Silver Bromide

BY S. E. SHEPPARD AND H. CROUCH

Communication No. 337 from the Kodak Research Laboratories

The problem of optical sensitizing has received much attention on the practical side, and the number of valuable sensitizing dyes has been greatly extended. The theory of the action has been attacked mainly from qualitative experimental evidence, or in pure speculation, but very little quantitatively.

The first questions are, how much dye is attached to silver halide and what is the nature of the combination?

Earlier studies by one of the authors on the isocyanine dyes¹ indicated that spectrophotometric determination in non-aqueous solvents should afford a satisfactory method of estimating these dyes even in quite small amounts. A study was made therefore of the partition of an isocyanine-orthochrome T-bromide between aqueous solutions and chloroform.

The partition was measured between chloroform and both M/20 (.05 molar) and M/100 (.0066 molar) phthalate buffer solutions. In these experiments 5 cc. chloroform were shaken with 20 cc. of aqueous buffer and the dye determined spectrophotometrically. It was found that there was a large specific salt effect, in that the partition coefficients,

$$C = \frac{\text{concentration in aqueous layer,}}{\text{concentration in chloroform}}$$

were much higher in the weaker buffer solutions of the same pH.

¹ S. E. Sheppard: Proc. Roy. Soc., 82A, 256 (1909).

TABLE I
 Partition Coefficient

pH	M/20	M/150	Water + Acid or Alkali
1.			—
2.			—
3.		—	11.5
3.2	.064		
4.0		2.7	.14
4.05	.013		
5.00	.003		.125
5.40		.89	
6.00	.003		
8.00		.10	.03
10.00			0.

The mechanism of this salt effect, whether a salting out effect on solubility or otherwise, requires further investigations, but is probably similar to the depression of solubility of non-electrolytes by strong electrolytes in general.

It appeared to be of interest to ascertain the effect of soluble halides on the partition between water and chloroform.

TABLE II

Molar Ratio of Dye to Halide	Concentration of Halide	Partition of Dye in Aqueous Layer		
		NaCl	KBr	KI
—	.0	.19	.19	.19
1:1	.0001N	.173	.175	.008
1:10	.001N	—	.040	—
1:100	.01N	.081	.005	—
1:1000	.1N	.070	—	—

Again 5 cc. chloroform containing 0.0010 gm. dye were shaken with 20 cc. aqueous solution.

These figures may represent the relative solubilities of the chloride, bromide, and iodide dye salts, on which is superposed the isohydric depression of solubility by a common ion, but require extension to determinations at various pH values.

State in Solution and Absorption Curves

The isocyanines¹ are converted by acids into a colorless form. At any given pH there is an equilibrium between the colored and colorless forms, and this can be followed by the absorption spectra in the visible and ultra-violet.²

¹ S. E. Sheppard: J. Chem. Soc., 95, 17 (1909); Phot. J., 48, 300 (1908).

² Cf. also R. Brode: J. Am. Chem. Soc., 46, 581 (1924).

The curves in Fig. 2 show the values obtained in aqueous solution. It will be seen that as the "colorless" form increases, the ultra-violet absorption increases.

The solubility of the dye in water diminishes with increasing pH, because while the colorless form seems to be quite soluble, the colored form is very little soluble in true solution, but readily disperses to colloidal solution. In

FIG. 1

acid solution the dye migrates to the cathode—corresponding to its dissociation into a large organic cation, and a halide ion. In alkaline solution (pH 13) no migration was observed in the electric field, but the experiments require extending, as the colloid micelles are probably charged. The tautomeric change is supposed to consist in the realignment of valencies in a conjugated chain of double bonds.

In organic solvents the solubility of the colored form is greater, the location of the absorption maximum slightly affected.

FIG. 2

FIG. 3

It is important to note that the partitions between aqueous solutions and chloroform indicate that the colored form is very little soluble in water, and also is much less polar than the colorless form. The partition may correspond to the following equilibrium system:—

or a hydroxyl may replace bromide (Br) with increasing OH^- ion concentration. Insolubilization of the colored form by salts, and halides, would give higher concentrations of dye in chloroform. The nature of the aqueous and chloroform solutions respectively is of great importance for the adsorption and sensitizing processes.

Adsorption to Silver Bromide

The method used was as follows: A suspension of silver bromide was prepared giving microscopically measurable grains. The grain-size frequency was determined by methods already described.¹ To reduce interference of the gelatin with the dye adsorption, the adsorption experiments were carried out at 50°C , the gelatin being only 1 per cent in concentration. This procedure is not entirely satisfactory, and a method of enzyme stripping of the gelatin has been developed for use in later work. Five cc. of the silver bromide emulsion containing a known amount of the silver bromide were diluted to 25 cc. with water, adjusted to a known pH with alkali or acid, and containing a known amount of dye, were added as concentrated alcoholic solution.

The reaction system was placed in stoppered amber glass bottles in a thermostat at 50°C and shaken for one to two hours. The silver bromide was then separated by centrifuging, at about 50°C .

The residual dye in the liquid was determined by extraction with CH_2Cl_2 and spectrophotometric determination. The dye actually adsorbed to the

silver bromide was also directly determined by dissolving the silver halide in thiosulfate solution, extracting the dye with chloroform and determining with the spectrophotometer. The sum of dye extracted from silver bromide and residual dye should equal the amount of original dye, and this was fairly closely fulfilled.

FIG. 4

Adsorption Function

The adsorption data obtained did not fit any modification of the (Freundlich) adsorption isotherm. The limit values in the horizontal part of the curves were taken as saturation values, and Langmuir's theory¹ of unimolecular layers applied in the form:

$$\eta = \frac{\tau \mu}{1 + \mu \alpha / v_1}$$

where η = gram molecules adsorbed per cm^2
 τ = average life of adsorbed molecule (time of relaxation)
 μ = gram molecules impinging on surface per cm^2 per sec.
 α = fraction of molecules which adhere
 v_1 = rate of evaporation (or solution) of molecules from surface.

Assuming $\alpha/v_1 = K$, is a constant for a given solid and adsorbant, then $\tau = n_0/NK$, where n_0 = number of atomic (molecular or ionic) spaces which can be filled

$$\begin{aligned} N &= \text{Avogadro's number} \\ &= 6.06 \times 10^{23} \end{aligned}$$

¹ J. Am. Chem. Soc., 40, 1368 (1919).

and

$$\mu = \frac{\sqrt{\frac{M}{2\pi RT}}}{M} \cdot C = \sqrt{\frac{1}{2\pi RTM}} \cdot C$$

$$= 1.2 \times 10^{-7} C$$

where C = concentration (\propto osmotic pressure p)

M = molecular weight of adsorbant

T = absolute temperature

R = gas constant 83.2×10^6 .

The equation was used in the final form:

$$\eta = \frac{K n_0 / N \cdot \mu}{1 + \mu K}$$

From X-ray data¹ the distance between Ag and Br atoms in the lattice of AgBr is 2.89 \AA.U. and the distance between centers of Br ions in an octahedral face is $\sqrt{2} \times 2.89 \text{ \AA.U.}$ and each ion occupies 14.45 sq. \AA.U. In 1 cm^2 surface of AgBr there are 6.93×10^{14} Br ions. From the integrated area-frequency curve the projective area per cc. of emulsion was 400 cm^2 , and the total surface 800 cm^2 .² Hence for 1 cc. AgBr emulsion we have $800 \times 6.93 \times 10^{14}$, *i.e.*, 5.55×10^{17} Br ions on the surface. And at a pH 5.5 there were 5×10^{-10} gram mols dye adsorbed at saturation per cm^2 . This gives $\frac{5 \times 10^{-10} \times 6 \times 10^{23}}{6.9 \times 10^{14}}$ molecules dye per Br ion, or 1 molecule dye per 2.3 Br ions.

Discussion

The adsorption curves obtained and the saturation values calculated are at first sight in agreement with the following theory. We may suppose that adsorption is due to the electrostatic attraction of a dye cation [D^+] to bromide anions of the AgBr surface. It has been shown by Trivelli and Sheppard³ that in AgBr crystals found in gelatin emulsions the octahedral surfaces constitute much the largest proportion. These surfaces will consist either of silver ions or bromide ions; in the presence of slight excess of bromide, of the latter.³ The limiting adsorption density would then be 1 dye cation or molecule to every bromide ion of the lattice surface.

The increase of adsorption density with pH may then be interpreted as due to increased concentration of the colored dye form, as cation. The second rapidly ascending portion of the adsorption curves, on this view, corresponds to the adsorbed dye (from molecular solution) acting at a certain density as nuclei for the precipitation of colloiddally dispersed dye. According to this, the position of the second ascending portion should approximately correspond to the true solubility of the dye in the aqueous solution of given pH.

¹ R. B. Wilsey: *Phil. Mag.*, **42**, 262 (1921).

² Assuming the grains to be flat tablets.

³ "Silver Bromide Grain of Photographic Emulsions," A. P. H. Trivelli and S. E. Sheppard, *Monographs of the Theory of Photography*, No. 1, Eastman Kodak Company (1921).

Although this interpretation appears reasonable, there are certain facts not in harmony with it. From the data on partition of the dye between aqueous solutions and chloroform, it appears as if the *colored form* is very slightly, if at all, soluble, in water, and also is very little ionized. As a non-polar, or less polar form, it shows correspondingly greater solubility in chloroform. If the dye is first adsorbed to the silver bromide as ionized, colorless¹ cation, and then transformed to the colored form at the prevailing alkalinity, it is difficult to see why the adsorption should increase with increasing pH, which lowers the concentration of the colorless form. An alternative hypothesis is that the colloiddally dispersed colored form is "salted out" on to the silver bromide by the surface excess of bromide ions, and that this first proceeds to a surface saturation, as the concentration of dye is increased, and then passes over into mechanical adsorption of the colloid dye at higher concentrations. In this case also it must be supposed that preliminary "patches" of adsorbed dye act as nuclei for further precipitation and adhesion.

A more complete investigation of the aqueous solutions of the dyes, and of the adsorption process is necessary before decision between ionic-molecular and colloid adsorption can be effected. Provisionally, the former hypothesis appears the more probable.

Sensitizing

Diffusion experiments into gelatin jellies at different pH values show that the diffusion rate increases with decreased pH. Experiments were run with dye solutions adjusted to a given pH and diffusing into cylinders of gelatin jelly at the same pH. After given periods, the jelly cylinders were cut in sections, and the total dye determined in each section. The plot of dye concentration against depth gives a measure of the diffusion. The results showed that the actual amount of dye passing the cross-section of gelatin jelly *surface* was approximately constant, as measured by total area of curve, but the slope was lower, the lower the pH, indicating that the diffusivity diminished with rising pH. This agrees with the tendency of the colored form to form colloidal micelles of low diffusivity.

Since it is the colored form which actually sensitizes, sensitizing by bathing with these dyes can sometimes be most uniformly effected by bathing in an acidulated solution of the dye, then adjusting with alkali to a higher pH (*cf.* absorption curves). The diffusion experiments indicate that at a pH 5 to 8 there is some dye present in the colored form in molecular solution, but the proportion relative to colloiddally dispersed dye diminishes as pH is increased.

From rough estimates, the amount of dye adsorbed at saturation appears to be very considerably higher than the amount taken up by silver halide for optimum sensitizing.

Provisionally, the mechanism of optical sensitizing, on the basis of the theory of adsorption proposed within, is as follows: Supposing that colored dye cation is electrostatically held to bromide ion, but that this original electrostriction passes into homopolar combination, in agreement with the con-

¹ That is, visibly.

clusion that the colored form is notably less polar than the colorless, on absorption of light by this in its own absorption region¹ an electron is freed, possibly from the bromide ion, and a silver ion reduced, or indirectly by the "reduced" dye cation.

This mechanism would give only one Ag atom for each dye molecule adsorbed to the silver halide. Recently² Leszynski has published evidence that (with erythrosin) up to 20 silver atoms may be photochemically reduced per dye molecule acting as sensitizer. He suggests that the photoelectron may travel some distance through the silver halide crystal, and effect a chain reaction of rather high efficiency, or that the reduced silver continues to act as an optical sensitizer.

As an alternative to this, it may be suggested that in the photodecomposition of adsorbed dye on silver bromide, the dye molecule is practically *exploded* with release both of several free electrons, and also of very active free radicals. The photochemical efficiency might then be considerably greater than unity, but would probably be a pronounced function of the *intensity* of the illumination.

That the optical sensitizing is connected with the photodecomposition of the dye is supported by the fact that the addition of silver ions to aqueous solutions of the dye greatly accelerates its decomposition (bleaching) by light. Our experiments on this indicated that below a molar ratio of about 1.5 Ag⁺ to 1 mole dye, little or no acceleration of decomposition was produced, while from this point the acceleration was approximately proportional to the silver concentration. Whether the apparent threshold is significant or not has not yet been determined.

THE BEHAVIOR OF DEAMINIZED GELATIN*

BY Z. C. LOEBEL**

According to the modern view, a protein is an amphoteric electrolyte capable of combining with hydrogen ion at the terminal amino groups and at the polypeptid linkages; and capable of neutralizing hydroxyl ion at the terminal carboxyl groups and at the polypeptid linkages. Recent investigations,^{1,29} have pointed to the close relationship between the properties of the proteins and their state of combination with acid and base.

The study of many of the properties of gelatin as a function of hydrogen ion concentration indicates a point of abrupt change occurs at its iso-electric point, pH 4.7. Thus at pH 4.7 there is a minimum of solubility, osmotic pressure, swelling, viscosity at 25°C., potential difference, optical rotatory power at and above 27½°C, and absorption of light; a maximum is found at this point for foaming and optical rotation below 27½°C. In 1922 Wilson and Kern² found that the swelling of buffered gelatin solutions gave a swelling-pH curve with a second minimum at pH 7.7. A second point*** of abrupt change has been found for other properties too; and the work of Davis and Oakes⁴ indicates a shift of the minimum for viscosity at 40°C from 4.7 at 25°C to about 8.0.

It was thought that an investigation of the behavior of gelatin, on whose molecular structure the free amino groups had been replaced by less reactive hydroxy groups might throw further light on the physical chemistry of the proteins. Such an alteration of the structure of the gelatin molecule should change its chemical and physical properties in a definite and measurable manner.

Materials Used

In all the experiments "Putmann's Silver Label" gelatin was used as a source of ordinary and deaminized gelatin.

The sodium nitrite, glacial acetic acid, ammonium sulphate, sodium hydroxide and hydrochloric acid used were of the ordinary C. P. variety and the two dyes for the iso-electric point experiment were used as received from the manufacturer.

The Preparation of Deaminized Gelatin****

Introductory

When a protein such as gelatin is treated with nitrous acid there is an evolution of nitrogen, presumably from the reaction of the nitrous acid with the

* Contribution from the Department of Chemistry, Columbia University, No. 565. Presented at the Philadelphia (1926) meeting of the American Chemical Society.

** This communication is an abstract of a thesis submitted by the author in partial fulfillment of the requirements for the degree of Doctor of Philosophy, Columbia University.

*** The two points always occur as geminated points: either both are maxima or both are minima.

**** The term "deaminized gelatin" as hereinafter used, refers to the gelatin which has undergone the nitrous acid treatment.

amion groups of the protein, the amino nitrogen being replaced by hydroxy groups. This reaction forms the basis of the Van Slyke method for the quantitative estimation of amino nitrogen. Nitrous acid was first used as a deaminizing agent for proteins in 1885 by Loew.⁶ Skraup⁷ and his co-workers have been largely responsible for perfecting the methods used in preparing deaminized proteins.

In 1914 Blasel and Matula⁸ deaminized gelatin according to Skraup's method and showed by hydrogen electrode measurements that the deaminized protein was still capable of combining with hydrochloric acid. Recently Hitchcock⁹ has published a quantitative study of the acid-combining capacity of ordinary and deaminized gelatin. He prepared the deaminized product by Skraup's method, but omitted the heating on the water-bath, a preliminary study indicating that the higher temperature induced a slight hydrolysis. Analysis of Hitchcock's preparation showed an exact agreement between the difference of the total nitrogen for ordinary and deaminized gelatin, and the amino nitrogen removed in the Van Slyke analysis; in each case 0.00040 equivalents of nitrogen per gram. Furthermore, the difference between the maximum combining capacity of the ordinary and the deaminized products for hydrochloric acid was nearly equivalent to the loss in amino or total nitrogen in the deamination.

Procedure

The deaminized gelatin was prepared after Hitchcock's method,⁹ brought to pH 4.0, dehydrated with alcohol, ground in a pebble mill, and passed through a 60-mesh sieve. The final product was left exposed to the atmosphere for a day to allow it to reach equilibrium with atmospheric moisture. It was a canary yellow, fibrous, solid and swelled in cold water like gelatin.

Analysis of the final product for total nitrogen by the Kjeldahl method gave 17.38 per cent while the original gelatin contained 17.96 per cent; a loss of 0.58 per cent or 4.1×10^{-4} equivalents per gram absolutely dry weight.

Ordinary iso-electric ash-free gelatin was prepared according to the method of Loeb,¹ ground in a pebble mill for 24 hours, passed through a 60 mesh sieve and left exposed to the atmosphere for a day to reach equilibrium with the atmospheric moisture.

The moisture in all samples of ordinary and deaminized gelatin was determined by heating in a 105° oven over night and all weights are reported on this moisture-free basis.

Determination of the Iso-electric Point of Deaminized Gelatin by the Dye Technique

Loeb¹ has shown that protein can combine with cations only on the alkaline side of its iso-electric point, and with anions only on the acid side. Hence deaminized gelatin should combine with the colored cation of a basic dye on the alkaline side, and the colored anion of an acid dye on the acid side of its iso-electric point. The iso-electric point as determined by the dye technique for gelatin, collagen and deaminized collagen shows good agreement with the values obtained by other methods.

TABLE I

Determination of Iso-Electric Point of Deaminized Gelatin

Acid Black	Fuchsin	pH of solution
Deep Blue	'Yellow	3.6
"Green	'Yellow	3.8
"Green (slight)	Reddish	4.0
'Yellow	Red (deep)	4.2

'—color of deaminized gelatin.

"—due to yellow of deaminized gelatin plus the blue of the dye.

Employing the dye technique as used by Thomas and Kelly²⁸ for collagen, the results given in Table I were obtained with Acid Black as acid dye and Fuchsin as basic dye.

These results indicate the iso-electric point to be at pH 4.0, checking the value obtained by Hitchcock⁹ for minimum of osmotic pressure.

Method of effecting Solutions

It was found that, because of the color and the turbidity of the solutions, a concentration below 0.5 per cent would be necessary in order to make optical rotation readings. It was planned to compare the different properties at a constant concentration and after a preliminary study, 0.4760 per cent was found most satisfactory.

The solutions were made up as follows: To 0.4760 gms. of sample in a 100 cc. standard flask, 10 cc. of distilled water were added, then varying amounts of acid or alkali and finally enough distilled water to reach the 100 cc. mark. After remaining at room temperature for one hour to allow the sample to swell, the flask was placed in a water-bath at either 50°C or at 75°C for five minutes, removed, inverted slowly five times and replaced in the same bath for fifteen minutes. The flask was then kept in a 25°C water-bath for ten minutes and was ready for use.

All pH values recorded in this report were obtained with the aid of a saturated KCl-calomel half cell junction with the solution being effected through a saturated salt bridge. pH was calculated from the equation, $\text{pH} = (E - 0.2466)/0.000198T$. Measurements were made at room temperature, which was recorded in each case.

Viscosity of Deaminized Gelatin

It will be recalled that Loeb's¹ viscosity-pH curves of gelatin at 25°C indicate a minimum of viscosity at the iso-electric point, pH 4.7. The viscosity-pH curves of Davis, Oakes and Brown³ at 25°C indicate no minimum at pH 4.7 while the viscosity-pH curves of Davis and Oakes⁴ at 40°C give no minimum at 4.7 but give one at about 8.0. Loeb's solutions were effected by heating to 45°C for ten minutes. Hitchcock¹⁴ found the viscosity-pH curve of gelatin at 40°C (solution effected by heating to 40°C) to be similar to that obtained by Loeb, with a minimum at pH 4.7.

Blasel and Matula⁸ measured the viscosity of deaminized gelatin but no valid conclusions can be drawn from their results because their observations were made at such wide intervals of pH.

Two groups of experiments on viscosity of deaminized gelatin were performed; in the first the solution was effected at 50°C and in the second the solution was effected at 75°C. In the first group, 5 cc. of each solution was pipetted into three Ostwald viscosimeters which were placed, respectively, into water-baths regulated at 10°C, 25°C and 50°C ($\pm 0.1^\circ\text{C}$), and after fifteen minutes the viscosities were measured. In the second the same procedure was followed except that the determinations at 10°C were omitted.

2.9	1.411	0.8389	7.3	1.965	1.169
3.3	1.367	0.8199	7.4	1.995	1.182
3.7	1.264	0.7465	7.9	2.000	1.185
4.0	1.179	0.7038	8.3	1.933	1.175
4.4	1.269	0.7276	9.2	1.861	1.118
4.7	1.361	0.7998	9.9	1.754	1.050
5.5	1.787	1.066	10.3	1.752	1.051
5.9	1.872	1.113	11.0	1.520	0.9123
6.2	1.987	1.190			

The results are given in Tables II and III and plotted in Fig. 1. The viscosity is reported as "Viscosity Ratio" V_t :

$$V_t = \frac{\text{Time in seconds at temperature } t \text{ for deaminized gelatin}}{\text{Time in seconds at } 25^\circ\text{C for water}}$$

FIG. 1

0.4760% solutions of:

- *Deaminized Gelatin—Solution effected at 50°C . Viscosity at (a) 10°C , (b) 25°C , (c) 50°C
- *Deaminized Gelatin—Solution effected at 75°C . Viscosity at (d) 25°C , (e) 50°C
- *Gelatin—Solution effected at 75°C . Viscosity at (f) 25°C , (g) 50°C

Although turbidity at pH 4.0 of solutions effected at 50°C permitted no viscosity measurements at this point, the direction of the curves on both sides shows a distinct tendency to locate the minimum at this point.

It will be noted further that:

(a) Each curve, whether the solutions were effected at 50°C or 75°C , or whether the viscosities were determined at 10°C , 25°C , or 50°C , is similar in shape.

- (b) Each has a minimum at its iso-electric point, pH 4.0
- (c) In each the rise on the alkaline side is greater than on the acid side.
- (d) Each has a second minimum at pH 7.3.
- (e) Each has maximums at pH 2.9, 6.5 and 7.9.

In Table IV and Fig. 2 are given the results of a series of experiments with gelatin solutions at 25°C and 50°C, which were of the same concentration as those of the deaminized gelatin described above (0.4760%). The solutions were effected at 75°C, the same technique as used for the viscosities described being employed. These curves and the curves found by Loeb at 25°C and by Hitchcock at 40°C show many points of similarity with those of deaminized gelatin:

(a) Each of the gelatin curves is similar in shape, independent of temperature of effecting the solution.

(b) Each has a minimum at the iso-electric point. In the deaminizing reaction amino groups are replaced by less basic hydroxy groups, and it is thus expected that with deaminization there should be a shift of the iso-electric point, to the acid side, as does occur.

TABLE IV
Viscosity of Gelatin Solutions at Varying Temperatures
and Hydrogen Ion Concentrations

0.4760% gelatin solutions
Solutions effected at 75°C

pH	V _{25°C}	V _{50°C}	pH	V _{25°C}	V _{50°C}
2.2	1.653	0.9348	5.0	1.226	0.7204
2.8	1.759	1.041	5.7	1.446	0.8152
3.3	1.820	1.062	7.0	1.517	0.8898
3.6	1.749	1.005	8.8	1.549	0.9135
4.4	1.361	0.8057	9.6	1.565	0.9240
4.6	1.282	0.7500	10.2	1.612	0.9502
4.7	1.157	0.6718	10.9	1.646	0.9739

(c) With gelatin the rise on the acid side of the iso-electric point is greater than that on the alkaline side; the reverse is the case with the deaminized gelatin. Comparing the 25°C and 50°C curves, it is seen that deaminization does not affect the viscosity at the iso-electric point, but lowers it on the acid side and raises it on the alkaline side; the rise on the alkaline side being very steep.

Thomas and Foster¹⁵ report a similar steeper rise of swelling with deaminization of collagen. They suggest as a possible explanation that the hydroxy groups which have substituted the amino groups are acidic in character. This would result in the formation of a greater amount of sodium salt on addition of sodium hydroxide and thus cause greater swelling.

The same explanation may be applied to account for the anomalous behavior of viscosity with deaminization of gelatin. Einstein's theory¹ holds that the viscosity is a linear function of the relative volume occupied by the

solute in the solution. The volume size of the protein solute, according to Loeb, would be dependent upon the swelling and osmotic forces which are governed by the Donnan Theory. It has been shown by Blasel and Matula⁸ and by Hitchcock,⁹ that deaminized gelatin combines with less hydrochloric acid than does gelatin. Then, following Loeb's theory, deaminized gelatin should have a lower viscosity than gelatin on the acid side, as is actually the case. In a later section a greater base-combining capacity is shown for the deaminized product, thus accounting for the greater viscosity on the alkaline side.

(d) The maximum on the acid side of the iso-electric point for gelatin is at pH 3.2, while that for the deaminized is at pH 2.9, indicating again a shift to the acid side.

(e) The second minimum for deaminized gelatin is at pH 7.3; that of gelatin is at 7.7; showing still another shift towards the acid side. A more complete discussion of the second point of abrupt change must be left to a later section.

Optical Rotation of Deaminized Gelatin

C. R. Smith postulated that there is a close relationship between the mutarotation of gelatin and its power to jellyfy. Prolonged heating on a water-bath causes a gelatin solution to lose both its power to jellyfy and to mutarotate. Kraemer and Fanselow¹² studied the optical rotation of gelatin solutions of varying hydrogen ion concentration at different temperatures, using the mercury light as a source of illumination. Their results of optical rotation as a function of pH show a minimum both at pH 4.7 and at about pH 8.0 for temperatures of $27\frac{1}{2}^{\circ}\text{C}$ and above, and show a maximum at the same points for temperatures below $27\frac{1}{2}^{\circ}\text{C}$.

It was planned to study the optical properties of deaminized gelatin and to compare them with those of ordinary gelatin.

TABLE V

Optical Rotation of Deaminized Gelatin at Varying pH and Temperatures

5.7	5.4	4.7	4.1	11.6	5.1	4.5	4.4
6.2	5.3	4.5	4.2				

Procedure

The solutions for the optical rotation experiments were prepared as described above, the solution being effected at 50°C. The solutions were polarized in 2.2 cm. jacketed tubes, water respectively at 10°C, 25°C and 50°C ($\pm 0.3^\circ\text{C}$) being pumped through the jackets. After 15 minutes at the proper temperatures, readings were taken. The instrument used was a Schmidt and Haensch saccharimeter, with a dichromate filter. White light was used as a source of illumination. The direct readings (negative degrees Ventzke) of 10°C, 25°C and 50°C are tabulated in Table V and plotted as a function at pH in Fig. 2.

FIG. 2

Effect of temperature and pH on the optical rotation of 0.4760 per cent solution of deaminized gelatin.

(a) = 10°C

(b) = 25°C

(c) = 50°C

Because of the turbidity and color no readings could be made at pH 4.0. The curve for 10°C readings shows a minimum at pH 2.9 and a tendency to form a maximum as the pH approaches 4.0. On the alkaline side of pH 4.0 the rotation falls off with increasing pH. At 25°C and 50°C the rotation is almost constant for each respective temperature. Unfortunately, the color and turbidity do not permit the use of higher concentrations which might magnify any deviations, and detect any mutarotation.

Surface Tension and Foaming of Deaminized Gelatin

Like gelatin, deaminized gelatin solutions foam on shaking. The adsorption film theory advanced by Bancroft is founded on Gibbs' statement that any substance which lowers the surface tension of a liquid must concentrate in the surface, thus forming a film and preventing the coalescence of the gas bubbles. Accordingly, gelatin and deaminized gelatin should foam most

at the points where the surface tension is least. Bogue²⁰ reports that the foaming of gelatin is a maximum at its iso-electric point. Johlin²⁶ finds its surface tension is a minimum at this point.

Surface tension

Surface tension measurements were made with the Du Noüy²⁷ tensiometer. The solutions, of 0.4760 per cent concentration, were made up by the same

FIG. 3

Effect of pH on the surface tension of 0.4760 per cent solution of deaminized gelatin and effect of pH on the foaming of 0.4760 per cent solutions of gelatin and deaminized gelatin.

technique as described above, solution effected at 50°C. Two cc. of each solution were pipetted into respective 4 cm. watch crystals and left at room temperature for one hour. During this hour it was covered with an inverted Petri dish. Because of the exposed surface of the alkaline solutions it can not be claimed that the pH values are accurate. However, they are not sufficiently far removed to prevent the indication of the general direction of the surface tension change with pH change.

The usual precautions of flaming the pipette, watch crystals and platinum ring were taken. The apparatus was calibrated against water at 23°C giving the value of 73 dynes per cm. The results, given in Table VI and plotted in Fig. 3, indicate a minimum at pH 4.0, a maximum at pH 2.9, which remains constant with further decrease of pH; and a maximum at about pH 6.5, which remains constant with further increase of pH.

TABLE VI
Surface Tension and Foaming of Deaminized Gelatin
at Varying Hydrogen Ion Concentration

pH	Surface Tension at 23° C Dynes/cm.	Foaming at 23° C cm.	pH	Surface Tension at 23° C dynes/cm.	Foaming at 23° C cm.
1.5	61.8	1.4	4.7	58.7	2.1
2.3	61.8	1.9	5.5	62.1	2.0
2.9	61.8	1.6	6.5	66.3	1.7
3.3	61.5	1.8	7.4	65.2	1.6
4.0	57.2	2.3	10.3		1.3

The foaming experiments were performed with the same solutions. Ten cc of each solution was added to respective 15 cc graduated test tubes and shaken all together, and the volume of foam read off. The results are recorded in Table VI and plotted in Fig. 3. They show a maximum at pH 4.0 and a minimum at pH 2.9. The curve obtained by Bogue is inserted for comparison. Although absolute values cannot be compared here, the general trend of the two curves show several interesting differences. Both curves show a maximum at their respective iso-electric points, but the gelatin curve has a second maximum on the alkline side, while the deaminized gelatin has the corresponding maximum on the acid side.

It will be noted that the surface tension in each case is lower than that of water and that the greatest lowering point of the surface tension curve is at the iso-electric point and corresponds with the highest point of foaming. These results are in conformity with the adsorption film theory, and are similar to those of Bogue and of Johlin for gelatin.

Titration of Gelatin and Deaminized Gelatin with Sodium Hydroxide

In a preceding section it was pointed out that the increase of viscosity on the alkaline side of the iso-electric point with deaminization is very likely due to the acidic nature of the hydroxy groups¹⁵ that replaced the amino groups. If this is true, the base-combining capacity of deaminized gelatin should be greater than that of gelatin by an amount equivalent to the replacing hydroxy groups.

To obtain comparable results both gelatin and deaminized gelatin were titrated. Samples equal to 0.4617 gm. absolutely dry weight were used; varying amounts of 0.1012N sodium hydroxide added and the pH determined electrometrically. A single sample was employed for each titration curve, the original volume being 25.30 cc. Preliminary results indicated that to adjust the pH of gelatin and deaminized gelatin to pH 7.0 required respectively 1.43 cc and 3.01 cc of the sodium hydroxide used. To keep the volumes at pH values above 7.0 more nearly constant, 1.58 cc (the difference between 3.01 and 1.43) of water was added to the gelatin sample.

The results are given in Table VII and plotted in Fig. 4.

*cc of exactly 0.1N NaOH required to adjust pH from 4.00 to that recorded in the last column.

** 0.10 cc 0.1N HCl required.

Examining the slopes of the first part of each curve, rising from their respective iso-electric points, it is seen that the slope of the curve for the deaminized sample is steeper.

This first portion of the curve for the deaminized gelatin rises to a higher value than that of the gelatin, indicating that the hydroxy groups begin to combine with sodium hydroxide directly beyond the iso-electric point. The sudden rise in viscosity directly beyond the iso-electric point is thus accounted for.

There is a change of slope at pH 7.5 for the deaminized gelatin which corresponds to a similar point for the gelatin at pH 7.7; it is interesting that pH 7.7 corresponds to the second point of abrupt change of the properties of gelatin.

At pH 7.5, 0.4617 gm of deaminized gelatin combines with 3.24 cc 0.1N sodium hydroxide.

At pH 7.7, 0.4617 gm of gelatin combines with 1.40 cc 0.1N sodium hydroxide.

The difference is 1.84 cc 0.1N sodium hydroxide.

For 1 gm this difference is 4.0 cc 0.1N sodium hydroxide or 4.0×10^{-4} equivalents.

FIG. 4

Titration Curves for 0.4617 gms of originally isoelectric:

- a) Gelatin and
- b) Deaminized Gelatin with N/10 NaOH

The Kjeldahl nitrogen of the

gelatin	17.96%
deaminized gelatin	17.38%
difference	.58% or 4.1×10^{-4}

equivalents nitrogen per gm. showing very good agreement with the difference of their base-combining capacity.

Examining the slope of the two curves beyond pH of 11, it may be seen that there exists a constant difference of about 4.0×10^{-4} equivalents of sodium hydroxide per gram dry substance. This may be construed to mean that the base-combining capacity for the deaminized gelatin is equal to that of gelatin plus 4.0×10^{-4} . Taking the value of the base-combining capacity of gelatin as found by Loeb¹¹ and Hitchcock¹⁰ at 5.7×10^{-4} , that for deaminized gelatin would be 9.7×10^{-4} equivalents per gram.

The Second Point of Abrupt Change

Several properties of gelatin, studied as a function of the hydrogen ion concentration, give curves of the same type as the viscosity curves. Some of these properties have been studied in the unbuffered range. Wilson and Kern² found a second minimum for swelling of buffered gelatin at pH 7.7. Higley and Mathews¹⁶ found a second minimum at the same point for absorption of light. Kraemer and Fanselow¹² and also Velles and Vellinger¹³ found a second point of abrupt change for optical rotation.

There seems to be only four proteins which show these double geminated points. They are collagen, deaminized collagen, gelatin and deaminized gelatin.

C. R. Smith⁷ postulated two forms of gelatin in solution, a "sol" form stable at temperatures above 35°C and a "gel" form stable at temperatures below 15°C, while at temperatures between, the existence of both in equilibrium. The work of Smith and Lloyd¹⁷ shows that the change from "gel" to "sol" form takes place with increase of Sørensen value of the solution. Wilson and Kern suggested that the two forms had different iso-electric points, the "sol" form at pH 7.7 and the "gel" form at 4.7; and that a preponderance of either one would determine the behavior.

Support for this idea is found in the work of Thomas and Kelly^{18, 19}. In studies of the rate of fixation of tannin by hide substance at room temperature¹⁸ as a function of hydrogen ion concentration of the solutions, they showed that the degree of fixation at a maximum at pH dropped to a minimum at pH 5; (the iso-electric point) rose again when a pH of about 8 was reached and then abruptly fell off with further increase in alkalinity. Since the tannin particles are negative, the decrease in rate of fixation from pH 3 to 5 was readily explained by the Procter-Wilson theory as due to the decreasing positive charge of the collagen. The rise in rate of fixation from pH 5 to 8 was unexplainable except on the basis of a shift of the iso-electric point. Thomas and Kelly¹⁹ repeating the same work at 40°C obtained no minimum at pH 5 and conclude, therefore, that the collagen exists in two modifications analogous to the "sol" and "gel" forms of gelatin; the iso-electric points of the collagen being at pH 5 and at 8.

With gelatin the evidence is more conflicting. To begin with, the exact location of the transition temperature, "gel" to "sol," is uncertain. C. R. Smith says it is at 35°C. Davis and Oakes place it at 38.03°C and Kraemer and Fanselow place it at 27½°C. Bogue,²⁰ on the other hand, says it depends on the concentration, heat treatment, pH and previous history.

Although Davis and Oakes report no minimum for the viscosity-pH curves of gelatin at pH 4.7 at 40°C and do report one at pH 8.0, it cannot be said to represent a shift of the minimum due to the temperature. Davis, Oakes and Browne using the same technique as Davis and Oakes, found the viscosity-pH curves of gelatin at 25°C gave no minimum at 4.7 either.

It was at first thought that the difference in method of effecting solution employed by Davis and his co-workers might be the cause for the difference in results. The matter was gone over with Dr. Davis and he determined the viscosities of two series of gelatin solutions, one series being treated as in his two papers—by heating on a hot plate for 20 minutes with continuous stirring till the solution reached 75°; the other series being treated in a manner similar to that employed in this research. His results indicated that the same qualitative results were obtained by either treatment.

The interpretation that has been placed on the work of Davis et al. has been that the minimum of viscosity at pH 4.7 at 25°C shifts to pH 8.0 at 40°C. Apparently the gelatin used by them did not have its iso-electric point at pH 4.7 as did that of Loeb, Hitchcock and that used in this research. Hitchcock's results for gelatin at 40°C and those reported in this investigation for gelatin and deaminized gelatin at various temperatures indicate no change of minimum with change of "gel" to "sol" form.

Loeb¹ postulated that the large changes of viscosity with pH of gelatin solutions at 25°C were due to two factors, the great magnitude of viscosity of gelatin solutions and the swollen micellae present. While such a theory is tenable enough for lower temperatures, it can hardly hold for higher temperatures, like 50°C. However, as a matter of pure speculation, it might be suggested the viscosity of gelatin is dependent upon a solution structure²¹ which in turn is dependent upon swelling forces, and therefore, according to the Donnan Theory, dependent upon osmotic force.

In the viscosity experiments of gelatin and deaminized gelatin, the solutions of which were effected at 75°C, no shift of minimum was observed. A preliminary experiment with gelatin solutions at different pH, but in which the solutions were effected by heating at 80°C for one hour, indicated no shift of the minimum.

Although the above evidence indicates no shift of the minimum of gelatin and deaminized gelatin, there is every indication of the existence of the second point of abrupt change of properties. Wilson and Kern's idea of this point as a possible iso-electric point of the "sol" form finds further support in the work of Miss Lloyd.¹⁷ She found that the "gel"- "sol" equation, brought about with increase of pH is reversible if sufficient acid is added. She offers the following explanation: "Brailsford Robertson²² has suggested that acids and bases attached themselves to protein molecules at the -COHN- linkage. He points out that this linkage may exist as an enol linkage -C-N- or as a

¹ Private communication.

keto linkage $\begin{array}{c} \text{—C—N—} \\ \parallel \quad | \\ \text{O} \quad \text{H} \end{array}$ and favors the enol-form since it offers a point of

attachment to both acids and bases. A more probable explanation seems to be that under the action of acids gelatin goes over to the keto-form, and under the action of bases to the enol-form." If this theory is correct, all proteins should show these geminated points of properties. Although only four are reported to have the two points, a more extensive study should be made with the thought of their possible existence in other proteins as well.

The likelihood that the second point is the result of hydrolysis is small. Measurements by Bogue²⁰ and by Northrop²¹ show that the rate of hydrolysis of gelatin at different pH is almost a constant for the same temperature. Northrop found the rate of hydrolysis is ten times more rapid at 65°C than at 40°C. It might be argued that the iso-electric point of these hydrolytic products is at pH 7.7. However, the experiments in this research indicated no shift of the minimum of viscosity with higher temperatures.

Knaggs and Schryver¹⁵ conclude, after careful attempts in purifying gelatin to obtain a product of constant composition, that there is no reason for regarding gelatin, even after elaborate methods of purification, as a chemical entity. This suggests another possible cause for the presence of the two points as due to the predominating effect of first one group and then another group of substances present in the gelatin.

There seems to be an indication of a relationship between the chemical nature of gelatin and deaminized gelatin, and the second point of abrupt change of properties. The titration curve of gelatin with sodium hydroxide has a point on inflection at about pH 7.7, and that of deaminized gelatin at about 7.5; the former point corresponding to the point of second minimum of swelling of gelatin as found by Wilson and Kern, and the latter almost corresponding to the second minimum of viscosity of deaminized gelatin as found in this research.

However, until more experimental work is done, the cause for the existence of the second point must remain a matter of speculation.

The author expresses his appreciation to Dr. A. W. Thomas for advice and criticism during the prosecution of this investigation.

Summary

A study of the behavior of a deaminized gelatin has been made and compared with that of gelatin.

The iso-electric point of deaminized gelatin is found by the dye technique at pH 4.0. The optical rotation, viscosity, surface tension and foaming of the solutions, are studied as function of hydrogen ion concentration. The optical rotation at 10°C and the foaming at room temperature are at a maximum at the iso-electric point. Surface tension is at a minimum at this point. Whether the solutions were effected at 50°C or at 75°C, or whether the viscosities were run at 10°C, 25°C, or 50°C, the viscosity-pH curve of deaminized gelatin was of the same shape, showing two minima, at pH 4.0 and pH 7.3.

Ordinary gelatin solutions effected at 75°C gave viscosity-pH curves at 25°C and 50°C, similar to those obtained by Loeb at 25°C, with a minimum at the iso-electric point.

Titration of deaminized gelatin and gelatin with sodium hydroxide indicates that the hydroxy groups which replace the amino groups in deaminization are acidic in character. The difference in the base-combining capacity of the two substances is equivalent to their difference in nitrogen content. The results indicate that the base-combining capacity of deaminized gelatin is 9.7×10^{-4} equivalents per gram.

The second point of abrupt change of properties is discussed.

THE ELECTROCHEMICAL BEHAVIOUR OF SILICATE GLASSES III*

CATHODE AND ANODE GASES**

BY M. J. MULLIGAN, J. B. FERGUSON AND J. W. REBBECK

Cathode Gas

When an electric current is passed through the walls of a soda-lime glass tube containing mercury as cathode, a film of gas may form at the mercury-glass interface and once formed will disappear in time if the direction of the current be reversed. This phenomenon was first studied by Rebbeck and Ferguson¹ who found that the gas consisted of hydrogen with a little oxygen. They also determined many of the conditions essential for gas production and disappearance.

The process of gas disappearance is such a curious one that a photographic record was made in order to dispel any illusions there might be in regard to the true nature of it. Marks were etched on the outer surface of several tubes and the marked parts were photographed at different stages of the electrolysis. When the bubbles were in focus, the marks were not and hence appeared blurred in the photographs. One series of these is shown in Plates I to IV. This series was taken by Ferguson and Ellis.²

The plates show that upon current reversal the individual bubbles became smaller and some disappeared entirely. The reappearance of the gas indicated by Plate IV seems to be in no way related to the original gas film. During this stage of the electrolysis a number of chemical reactions take place. These will be discussed in a later paper on the formation of solid electrolytic deposits in glass.

The disappearance of gas on current reversal may in part be explained on the assumption that the sodium enters the glass from the sodium hydroxide film which was formed at the interface during the evolution of gas and that the water was re-formed and sorbed by the glass. In support of this suggestion, we found that hydrogen gas will disappear in the presence of sodium hydroxide but not in its absence. Bubbles of pure dry hydrogen were trapped between the mercury and the glass during the filling of a new soda-lime glass tube with mercury by distillation³ and the tube electrolysed, mercury anode, with 110 volts at 100°C for 70 hours. The gas did not disappear. A similar tube was

² Ferguson and Ellis: Trans. Roy. Soc. Canada, (3) **19**, 34 (1925). (Abstract only.)

³ New glass signifies glass which has not been subjected to any especial treatment electrical, thermal or otherwise. The experimental procedure was similar to that used by Rebbeck and Ferguson.

first washed out with a dilute aqueous solution of sodium hydroxide and dried at 70°C by evacuation to 0.001 mm. mercury before trapping the hydrogen. Upon electrolysis under similar conditions for 72 hours, many of the bubbles disappeared and others became smaller. The experiments were carried out in duplicate and triplicate respectively.¹

A somewhat similar experiment with pure dry hydrogen was performed by trapping a small bubble in a well-annealed tube which was held in a horizontal

Plates 1-4

Gas Disappearance and Reappearance ($\times 100$).

Plate 1. A new soda-lime glass tube was electrolysed for 6.5 minutes at 95°C with 110 volts, mercury cathode.

Plate 2. The direction of the current was reversed and the electrolysis continued for 3.5 hours.

Plate 3. The previous electrolysis, mercury anode, was continued for 7.5 hours additional.

Plate 4. The mercury was made cathode and the tube electrolysed for 50 hours.

position, reducing the pressure until the bubble was several millimeters in diameter and then electrolysing with mercury anode at 150°C with 100 volts for 19 hours, at the same time slowly rotating the tube. The bubble did not appear to change. The pressure was increased to atmospheric and the electrolysis continued but with mercury cathode. No additional gas formed. When this experiment was repeated with hydrogen containing a little water vapour, on reversing the current, gas was produced in the form of a fine film which just covered the area traversed by the bubble during the rotation of the tube and did not extend beyond the edges of this area. This gas probably came from the reaction between the sodium from the glass and the sorbed

¹ The bubbles were identified by means of marks on the glass.

water since the hydrogen bubble did not progressively change in size during the electrolysis with mercury anode.

Cathode gas was previously observed with soda-lime glass and lead glass. It has since been obtained with Schott types 59^{III}, 16^{III}, 1447^{III}, 3818^{III}, 2814^{III}, 1003^{III} and Cavalier glass. A very long time elapsed before a visible film of gas was produced with the last mentioned glass and, in addition, those glasses which were heated in an oxy-gas flame in the preparation of the sample tubes required an exposure to moisture prior to the evacuation of the tubes and subsequent filling with mercury. Cathode gas, formed with 59^{III} and 16^{III}, disappeared in a normal fashion upon current reversal. Tests of this were not carried out with the other glasses.¹

If the initial formation of cathode gas on new soda-lime glass were the result of the action of sodium from the glass on the sorbed water, one would not expect to obtain gas with glass in which the sodium had been replaced with silver.² This conclusion was tested in the following manner. Silver was electrolysed into a new soda-lime glass tube from a melt of silver nitrate at 250°C using 110 volts for 7 minutes. The silver nitrate was removed; the tube was washed with nitric acid and distilled water, dried by evacuation and filled with mercury in the usual manner. It was electrolysed with mercury cathode at 100°C with 110 volt and no gas was visible after 60 minutes although a solid deposit formed at the interface which we assumed to be a mercury-silver compound. In a blank experiment, a tube containing no silver but subjected to the same heat treatment gave gas on subsequent electrolysis in 10 minutes and a similar tube through which sodium had been electrolysed at 330°C for 60 minutes from a sodium nitrate melt gave gas at the lower temperature in 17 minutes. However when silver was electrolysed into new soda-lime glass at 100°C from aqueous solution of silver nitrate, 0.02N, gas was produced using 110 volts at the same temperature.³

When well-annealed glass was substituted for new glass in the last experiment at 100°C, no gas was obtained but a solid deposit at the interface similar to that produced when a silver nitrate melt was initially employed, although the presence of moisture was indicated on a similar but unelectrolysed silver-containing tube upon treating it with sodium amalgam. The gas obtained in the experiment with new glass disappeared in a normal fashion on current reversal.

These experiments suggest that silver from an aqueous solution does not always uniformly replace the sodium in new glass although it may do so with annealed glass. The possible migration of hydrogen ions into glass was first

³ Silver was first observed to enter glass from aqueous solutions by Mulligan: *Trans. Roy. Soc. Canada*, (3) 19, 35 (1925); also a note in a paper by Horovitz: *Sitz. Akad. Wiss. Wien*, 134 IIa, 383 (1925).

studied by Rebbeck and Ferguson and their observations have more recently been supported by the work of Quittner.¹

Such migration may play some part in the phenomenon under discussion. The fact that gas formed on the new glass at 100°C when aqueous solutions of silver nitrate had previously been used, would disappear upon current reversal, points to the presence of sodium at the interface. This suggests that certain parts of the glass surface were impermeable to silver ions and that at these spots very little electrolysis took place, the potential gradient set up being only sufficient to form a very minute sodium-deficient layer. On current reversal, the sodium quickly reached the glass surface and reacted with the surface water. These spots would appear to be destroyed by annealing or by contact with a silver nitrate melt. The nature of them would seem to be bound up with the water content of the glass surface since both these treatments would tend to abstract the water. Also, Haber and Klemensiewicz² found that their glass electrodes behaved consistently as hydrogen electrodes only after they had steamed them for some hours. Horovitz after a careful study of the action of certain water-resistant glasses concluded that these acted as mixed electrodes and his work has been confirmed by others. Our observations although quite different in nature are in accord with his results.³

Rebbeck and Ferguson found that 1.2 volts was above that required to just produce gas. The following factors prevent an exact determination of this voltage. Conditions may not be the same at all points on the glass surface. Some minutes are necessary for the building up of the counter E.M.F. and there may be a lapse of time between the formation of gas and the production of visible bubbles. Once electrolysis starts the various contact potentials in the system may all change and one cannot readily determine the nature of each. However, in one series of experiments gas was produced when the difference between the initial contact potential for the whole system and the applied voltage did not exceed 0.8 volts.

Since the sorption of water is involved in the disappearance of cathode gas, the question as to whether the current assisted in this was investigated. Gas was produced on a tube of new soda-lime glass at 100°C with 110 volts for 20 minutes and then caused to disappear by further electrolysis for many hours with mercury anode. A small amount of sodium amalgam was then added to the mercury in the tube and the latter held at 100°C without electrolysis for a time. After 30 minutes no gas was visible but after 20 hours a small amount could be seen under the microscope. The amalgam treatment also gave much less gas with new, or moistened annealed, soda-lime glass which had been electrolysed with mercury anode for long periods of time at 100°C with 110 volts, than with the new glass which was subjected to the same heat treatment alone prior to adding the amalgam. Since the amalgam reacts with such electrolysed tubes to give a dark deposit, there was the pos-

¹ Quittner: Sitz. Akad. Wiss. Wien, 136 IIa, 151 (1927).

² Haber and Klemensiewicz: Z. physik. Chem., 67, 385 (1909).

³ Horovitz: Z. Physik, 15, 369 (1923), and Sitz. Akad. Wiss. Wien, 134 IIa, 335 (1925).

sibility that there was not enough sodium for both reactions. This was not the case since the amalgam treatment gave gas and deposit on similar electrolysed tubes when these were moistened after electrolysis, dried by evacuation, refilled with mercury and then treated with amalgam. If after a small amount of gas was obtained with the electrolysed tubes using sodium amalgam, the tubes were then electrolysed with the amalgam as cathode more gas was obtained than in the case in which the tube with the amalgam had simply been given the same heat treatment. The results indicate that water may move into or out of glass under the influence of an electrical current. This may in part account for the slow reappearance of gas on current reversal after it has been caused to disappear but it is probably not the most important factor in this.

Anode Gas

Rebbeck and Ferguson obtained no anode gas at the mercury-glass interface at temperatures up to 100°C with 110 volts applied when the glass was properly cleaned. Le Blanc and Kerschbaum¹ did not observe any such gas even at 320°C but on subsequent heating of their samples to the softening point gas was liberated at the anode side. This gas nearly equalled the amount calculated by them from the sodium liberated at the cathode on the assumption that the anion SiO_3 had decomposed to give oxygen. The discrepancies between the calculated and observed amounts were attributed by them to their inability to remove all the oxygen from the viscous melts.

With soda-lime glass, anode gas has been produced using 110 volts at temperatures above 275°C . In one case, the gas formed on a freshly annealed tube at 310°C and later disappeared, giving rise to a dark deposit at the mercury-glass interface. This deposit clearly indicated the positions of the original bubbles. It was insoluble in water but dissolved in nitric acid. When smeared on the glass, it appeared to consist of red and yellowish materials and was similar in appearance to the deposits of mercury oxides which formed on the upper portions of tubes containing mercury when these were heated to a high temperature. Below 275°C small amounts of gas were obtained but we could not be sure if the minute amounts were true electrolytic products. However, deposits similar to those obtained at 310°C were observed at these lower temperatures. At 100°C traces were obtained using 110 volts and definite deposits were formed on a tube electrolysed over night at 100°C with 220 volts.

When a tube of soda-lime glass was electrolysed with 110 volts at 450°C for a long time using a carbon anode, the anode side of the glass was filled with bubbles some of which had broken the anode surface. The cathode surface of the glass was not visibly changed. On heating this glass it swelled and gave rise to the pumaceous product. In general our glass behaved like that of Le Blanc and Kerschbaum, but appeared to give gas at lower temperatures. These workers may have lost some gas through the oxidation

¹ Le Blanc and Kerschbaum: *Z. physik. Chem.*, **72**, 468 (1910).

of the mercury and this may be an additional reason for their low results. The chief difference between their results and our own is the relatively low temperature at which anode gas was found by us to be liberated. This may be accounted for on the basis of glass composition since different glasses were used.

In conclusion we wish to thank Dr. Horovitz for the Schott glasses which he obtained for us.

Summary

1. New evidence has been submitted upon the formation and disappearance of cathode gas during the electrolysis of various glasses and on the permeability of glass to various ions.
2. Anode gas has been found to form at temperatures much lower than those previously reported.

Toronto, Canada.
October, 1927.

SOME PHYSICAL PROPERTIES OF AQUEOUS HYDROXYBENZENE SOLUTIONS

BY LLOYD E. SWEARINGEN

The mono, di- and tri-hydroxybenzenes form a class of substances important and peculiar unto themselves. The mono derivatives, as well as some of the di and tri derivatives are common substances met with in a number of widely different preparations and uses. In spite of their somewhat wide-spread usage, little work has been done on the physical properties of aqueous solutions of this class of substances. This is especially true of the di- and tri-hydroxy derivatives. Their solubility in water is known; the water-phenol system has been exhaustively studied; Skraup and Philippi¹ have studied the capillary rise of phenol-water solutions; Thiel and Roemer² have studied the acid properties of the phenols by electric titration methods. Morgan and Egloff³ have measured the surface tension of phenol-water mixtures by the drop weight method. Worley⁴ has measured the surface tension of phenol-water mixtures by the capillary rise method. More recently, Ferguson⁵ has determined the specific heats, the heats of mixing and the vapor pressures of mixtures of phenol and water.

In view of the small amount of physical data available for solutions of this class, the following measurements have been carried out with the view of contributing something to the knowledge of properties of this class of solutions. The surface tension, the density, the index of refraction and the viscosity of these solutions have been determined.

Experimental

Material

Water. The water used in these experiments was a good grade of conductivity water, twice distilled from acid permanganate and barium hydroxide, then collected and stored in well steamed and cleaned pyrex glassware.

¹ Monatsheft, 32, 353-72 (1911).

² Z. physik. Chem., 63, 711-61 (1908).

³ J. Am. Chem. Soc., 38, 844 (1916).

⁴ J. Chem. Soc., 105, 260 (1914).

⁵ J. Phys. Chem., 31, 757 (1927).

Procedure

A quantity of each of the above hydroxybenzenes, sufficient to make 200 c.c. of a 0.5 molar solution was accurately weighed out and then dissolved in the required amount of water. In the case of phloroglucinol, due to the small sample available, the solution prepared was only 0.0836 molar.

The surface tensions, densities, indices of refraction and the viscosities of the original solutions were determined. Then a definite quantity of each of the solutions was mixed with water in such proportion as to decrease the con-

FIG. 1

centration of the solute to 0.8, 0.6, 0.4, 0.2 of the original value, so that in this way a series of solutions of 0.5, 0.4, 0.3, 0.2 and 0.1 molar concentration was prepared for each of the hydroxybenzenes. The physical properties were then determined for each of the different solutions.

Density

The density of the different solutions was determined by the pycnometer method, using a Geissler pycnometer. The measurements were made at 25°C. and the value of $D_{4}^{25^{\circ}\text{C}}$ calculated. Table I gives a summary of the density

determinations. The values given are the averages of three determinations. The separate determinations differed by less than .05% from each other. Correction has been made for the buoyancy of the air. The variation in specific gravity with density is shown graphically in Fig. 1.

Viscosity

The viscosity measurements were taken at 25°C with a modification of the Ostwald-Poiseuille viscometer. The temperature could be controlled to within a 0.1°C. The time of outflow was measured with a stop watch, reading direct

FIG. 2

to 0.2 second. The usual precautions were taken in cleaning, washing and drying the tube. The viscosity measurements are given in Table II. The data given are averages of three separate determinations. The time for each determination within a series was reproducible to within 0.4 sec. For all solutions more than 100 sec. was required for outflow. For conversion to absolute units, the value (0.00894 c.g.s. units) of Bingham and Jackson¹ was used. The effect of concentration on the viscosity is shown graphically in Fig. 2.

Index of Refraction

The index of refraction was measured at 25°C with an Abbe refractometer. The temperature was constant at 25°C to 0.1°. The indices of refraction are given in Table III. The readings given are averages of four separate readings. The variation of the index of refraction with density is shown in Fig. 3.

Surface Tension

The surface tension measurements were made with a du Noüy Tensiometer. The instrument was calibrated with water at 25°C, a value of 74.46 dynes/cm being obtained for water at 25°C. 5 c.c. portions of the different solutions were placed in deep watch glasses and the glasses placed in a water bath at 25°C. The watch glasses were carefully cleaned and flamed before use. The readings given are the averages of six determinations. These readings were reproducible within 0.1 scale unit. The measurements are shown in Table IV and Fig. 4.

FIG. 3

Discussion

No irregularity is apparent in the data for the density of the solutions. Two of the three di-hydroxy derivatives, the meta (1:3) and the para (1:4) have almost identical densities, while that of the ortho (1:2) is but slightly greater at corresponding concentrations. Reference to Fig. 1 shows an almost linear relation between concentration and specific gravity. The densities of the different solutions can be calculated very accurately from the law of mixtures. If the equation for a straight line be written as $D = mC + D_0$, the densities can be calculated very accurately. D is the density to be found, m a

constant, characteristic for each substance, C the concentration in moles/liter and D_0 the value for the average density of the solution at zero concentration of solute. m is the value of dD/dC , the change in density with concentration. The values of m for the different hydrobenzene solutions are as follows:

	m		m
Phenol	0.0075	Hydroquinol	0.0210
Catechol	0.0230	Pyrogallol	0.0350
Resorcinol	0.0210		

FIG. 4
Surface Tension—Concentration Curves

An increase in the number of hydroxy groups in the benzene ring seems to produce an exaltation in the viscosity, as for all concentrations investigated, there is an increase in viscosity in going from the mono- thru the di- to the tri-hydroxy derivatives. The position of the hydroxyl group seems to have but little influence, as all of the di-hydroxy derivatives possess viscosities very nearly the same, the meta having a slightly higher viscosity than the ortho, which in turn has a viscosity slightly greater than the para derivative. The introduction of the third hydroxyl group tends to cause a considerable increase in the viscosity at all concentrations except the lowest, where all the viscosities are but slightly different from that of pure water. Viscosity con-

centration curves of the type shown in Fig. 2 are similar in character to those of approximately normal substances, showing little or no association or dissociation in water.

The index of refraction exhibits but little change with changes in density or concentration. The change is greatest with phenol, less with the di-hydroxy derivatives and still less with the trihydroxy derivative. The three di-hydroxy derivatives show but slight variation among themselves.

The surface tension values of the phenols in water determined by Skraup and Philippi are not available, but the order of decreasing rise given by these workers is as follows: Phenol, catechol and hydroquinol rise to about the same height. Resorcinol and pyrogallol give lower values in the order named. This order is the same as found in the present work, with the exception of the position of hydroquinol and resorcinol. The values of the surface tension of phenol and water in the present work are slightly greater than those reported by Morgan or Worley.

The surface tension values show considerable variation depending on the number and position of the hydroxyl groups. Each molecule of phenol is much more effective in lowering the surface tension of water than is a molecule of the di- or tri-hydroxybenzene. The di-hydroxybenzenes stand in the order, ortho, meta and para, in their ability to lower the surface tension of water. This order is the same as their order of increasing melting points. The highest melting point compound lowering the surface tension less than those of lower melting point. Pyrogallol lowers the surface tension of water but slightly. The melting point of pyrogallol is between the melting points of the meta and para di-hydroxy derivative.

As we go from benzene, which is but slightly soluble in water to phenol which is moderately soluble at room temperature, to the di- and tri-hydroxy derivatives, the enhanced solubility of these latter is usually ascribed to an increase in the number of hydroxyl groups in the benzene ring. The fact that water is a polar substance and the polar properties of the hydroxyl group have long been recognized.

Surface tensions of a series of similar substances will usually follow the same general order as the melting points, if solids, or the boiling points, if liquids. Other factors being the same, a molecule of phenol should be more effective in lowering the surface tension of water than a molecule of the di- or the tri-hydroxy derivative, due to the lower surface tension of the phenol. Fewer phenol molecules than di- or tri-hydroxybenzene molecules would need be concentrated in the surface to produce a given lowering in the surface tension of water.

0.02 mole of phenol produces as great a lowering in the surface tension of water as 25 times that much pyrogallol; as 20 times the para, 8.5 times the meta and 3.5 times the ortho di-hydroxy benzenes. Undoubtedly more of the highly capillary active phenol molecules are in the surface layer than are the di- and tri-hydroxy molecules at corresponding concentrations. Otherwise, it would be difficult to account for the appreciable lowering of the surface tension of water by phenol. The di- and tri-hydrobenzenes undoubtedly

have higher surface tension values than phenol and are incapable of lowering the surface tension of water to such a degree as phenol. But in view of the high concentration of the di- and tri-hydroxy derivatives required to produce a lowering corresponding to a small concentration of phenol, it is logical to assume a much smaller surface concentration of the di- and tri-derivatives than of phenol.

Evidently, the increased number of hydroxyl groups encountered in going from the mono to the tri derivatives produces a greater resemblance between the hydroxybenzene molecules and water, with the result that the di- and the tri-hydroxybenzene molecules concentrate less readily in the surface and more readily in the bulk of the solution.

Summary

1. The density, viscosity, index of refraction, and surface tension of aqueous solutions of hydrobenzenes have been determined at 25°C.
2. No pronounced effect due to the number or position of the hydroxyl groups has been found except in the case of surface tension.
3. The monohydric derivative is more effective than the dihydric derivative, which in turn is more effective than the trihydric derivative in lowering the surface tension of water.

Norman, Oklahoma.

NEW BOOKS

Physical Chemistry and Biophysics for Students of Biology and Medicine. By Matthew Steel. 23 × 15 cm; pp. x + 372. New York: John Wiley and Sons, 1928. Price: \$4.00. The subject is treated under the following headings: general introduction; the nature and structure of matter; general properties of matter; energy transformations in living matter; general nature of solutions; water, the greatest solvent; diffusion and osmotic pressure; the nature and behavior of electrolytes in solution; chemical equilibrium and the law of mass action; measurement of hydrogen ion concentration; the colloidal state of matter; catalysis and velocity of chemical reactions; dynamical physical chemistry of the cell.

This book is apparently written for use in an undergraduate medical school because the author says that "the treatment of the subject is based on the course in physical chemistry pursued by medical students at the Long Island College Hospital." Under these circumstances the book should have been kept as simple and as accurate as possible.

Instead of this the author says that "considerable attention is given to the modern conception of the nature and structure of matter because the composition of the atom is the keynote of the properties of matter in all the various states of aggregation. Without a knowledge of the present-day theories in regard to the nature and structure of the atom, it is impossible for the student to comprehend such topics as the cause of ionization, the nature of amphoteric electrolytes and their isoelectric points, hydrogen-ion concentration, Donnan's membrane equilibria theory, oxidation-reduction phenomena in the absence of free oxygen or hydrogen," p. v.

Hydrogen ion concentrations and amphoteric electrolytes were studied before anything was known about the composition of the atom. We can only marvel at the wonderful ingenuity of Donnan in deducing a relation which, by definition, he could not comprehend.

The author got much of his physical chemistry from H. C. Jones and he says that "in the chapter on the Colloidal State of Matter the researches of Jacques Loeb on proteins have received special attention owing to the far-reaching influence that Loeb's discoveries and conclusions have on all biological and medical problems." Even that does not account for all the characteristics of the book. The author must have thought of some things himself.

On p. 12 is the statement that "one of the types [of sulphur] crystallizes in rhombic crystals and the other in monoclinic crystals. Both have the same freezing-point and boiling-point." They don't have the same freezing-point and crystals don't have boiling-points.

There is no definite policy in regard to people. On p. 23 we read that "at the suggestion of Becquerel, Mme. Curie (Marie Sklodowska Curie), Professor of Physics at the Sorbonne, Paris, studied uranium minerals." The author means of course that Mme. Curie is now Professor of Physics. That is legitimate enough; but what is the student going to do when he reads, on p. 24, that "the first noteworthy evidence in regard to the true character of the radiations was presented by Sir Ernest Rutherford, Professor of Physics at the University of Manchester." Rutherford is certainly not at Manchester now.

On p. 62 is the statement that "chemists have decided to adopt eight grams of oxygen as the standard of comparison." On p. 65 is the paragraph that "matter occurs in different states or conditions known as *states of aggregation*. The three principal states of aggregation the *gaseous state*, the *liquid state*, and the *crystalline state*. There is another important modification of the latter two states, known as the *colloidal state*. In addition there are *amorphous solids*, *solid liquids*, and *liquid crystals*." That is helpful to the student.

It would take a good man to deduce, p. 67, the equation

$$pv = p_0v_0 (1 + 0.00367 t)$$

from the preceding two equations on the same page. It is just possible that the author did not know the intermediate steps and therefore skipped them. The reviewer could not discover the difference between v and V , p. 68. Nobody would guess, p. 71, that a and b in the

van der Waals equation are not really constants. The statement of Berthelot's law on p. 87 is a bit sweeping for a heading of general concept of energy. It might also be questioned whether "we owe much of our knowledge of chemical energy to the French chemist, Berthelot."

"With regard to the influence of the nature of the gas on the solubility, it may be said in general that the extremely soluble gases, like ammonia and hydrogen chloride, do not obey Henry's law in the matter of solubility, i.e., their solubility is not proportional to the pressure. This is undoubtedly due to their distinct basic and acidic properties which induce them to form compounds with the solvent. Thus, NH_3 unites with H.OH to form NH_4OH , and HCl unites with H.OH to form a hydrate, HCl.H.OH ," p. 108. It is not impossible that hydrochloric acid forms a hydrate, $\text{HCl.H}_2\text{O}$; but that is not the chief reason for hydrochloric acid not following Henry's law.

Under solutions of liquids in solids, p. 113, the author says that "solids also have the property of taking up many liquids in greater or less quantities. Many of the substances that we are accustomed to think of as solids are really mixtures of solids and water. Moreover, it is very difficult to obtain these solids free from water." One man's guess is as good as another's as to what the author is talking about."

On p. 116 no one would ever guess that the order of dissociating power of liquids does not always run parallel with the dielectric constant.

"Solutions of the second class, those whose osmotic pressure is greater than the values obtained in the first class, include the acids, bases, and salts, i.e., those substances that conduct electricity when dissolved in water, and some other solvents. Now, as these constitute a very large and important class of compounds, their failure to conform to the laws that apply to the first class prevented the general acceptance of van't Hoff's theory of solutions for a long time," p. 132. Since very few people read academy publications, the long time to which the author refers was a few days over two months.

On p. 134 is the statement that "there are several other theories of semipermeable membranes which have many data to back them up, but they are not as plausible as the *preferential solubility* theory." Regardless of what the reviewer may have said in the past, he is quite sure now that the copper ferrocyanide membrane does not owe its properties to preferential solubility. Without looking the matter up, the reviewer doubts whether Soret explained his phenomenon by establishing the relationship between diffusion and osmotic pressure, p. 144. It is usually believed that van't Hoff explained the Soret phenomenon.

On page 163 we read that "both the ampere and the volt are based upon another law as fundamental as Ohm's law, discovered by Faraday in 1833"; but we are not told what Faraday's law has to do with the volt. On p. 206 the author takes a running leap into the unknown and says that "the solution pressure of a metal remains constant so that any change in potential is due entirely to a change in osmotic pressure." He evidently believes that there is a definite relation between the calculated pH and the hydrogen ion concentration. On p. 210 he says that "if, for example, $C_1 = 1$ gram-equivalent of H^+ ion per liter, and if we represent C_2 by H^+ , we can obtain the value of the unknown hydrogen-ion concentration by means of the equation $E = 0.058 \log_{10} (1/\text{H}^+)$ ". This is undoubtedly true; but there is nothing to show what solution contains exactly one gram-equivalent of hydrogen ion per liter. Even if the author knew one, how would he get anybody else to agree with him and does the equation hold for normal solutions? Are we justified in saying, p. 212, that "under normal conditions a potential of $+0.56$ volts is developed in the calomel electrode?

Under "Preparation of Colloidal Solutions," p. 231, there is nothing to show under what conditions or why a colloidal solution is formed. It is not true, as the author implies, p. 233, that one can remove the peptizing agent from a sol by dialysis and still have a sol. It is possible to remove some of it; but when you take away the last straw, the horse dies.

"When emulsoids are added to suspensoid sols the general reaction is that described under the caption of "protective colloids." Some precipitation may take place if they are oppositely charged, but the reaction is never complete, and as rule the suspensoid acquires the charge of the emulsoid owing to the coating effect. No generalizations have been established," p. 265. The author could have done better than this.

On p. 280 is the extraordinary statement that "emulsions are of two kinds: (1) a small quantity of a liquid in suspension in a large amount of another liquid; and (2) a large amount of one liquid suspended in another liquid. In the second class the continuous phase must consist of a solution of a colloid, such as soap, protein, or saponin." The author has heard of oil-in-water and of water-in-oil emulsions because he refers to them later, p. 356. What he is trying to do here, though unsuccessfully, is to differentiate between an emulsion stabilized by an adsorbed ion and one stabilized by an adsorbed substance.

The reviewer is sceptical about the statement, p. 284, that "the effect of heat on a gelatin sol is very different from its effect on a protein sol. Both gelatin and agar dissolve in hot water. The solution on cooling sets to a jelly. If a rather concentrated gelatin sol is heated and then permitted to cool, the jelly is not reconverted into a sol when the temperature is raised again, unless more water is added."

The reasoning about proteins is beautifully simple, p. 284. There are some free amino and carboxyl groups in the proteins and consequently they must form salts. Since they form salts there must have been some free amino and carboxyl groups. The treatment of the Hofmeister series, p. 290, is almost equally good. Loeb worked under conditions of dilution for which only the adsorption of hydrogen and hydroxyl ions was important and drew the conclusion that the Hofmeister series was meaningless. Other people worked under more intelligent conditions and found the Hofmeister series. The author points out triumphantly that these people do not, however, deny the validity of Loeb's work. What they denied and still deny is the validity of Loeb's conclusions. Procter, p. 298, "assumed a gelatin sol to contain gelatin ions which cannot diffuse into the surrounding water through the surface of the gelatin." We are not told why gelatin ions should not form on the outside.

The author is unnecessarily vague about jellies, p. 306. He says that most authorities consider a jelly as a two-phase system in which the dispersing agent is a solid and the dispersed phase a liquid. Four lines later he says that a concentrated gelatin jelly consists of "a solid phase, rich in gelatin, which forms a meshwork in the interstices of which is imbedded a very much more liquid second phase." If we have a mesh-work, we cannot speak of a dispersing and a dispersed phase, because each phase is continuous. It is what the reviewer has called an interlacing system. The author would hardly say that air is dispersed in a coil of wire fence no matter how small the meshes were.

There are good passages in the book. The reviewer found two that interested him particularly. "The red blood corpuscles are an easy cell to work with, on account of the ease with which they can be obtained. The contents of these cells is enclosed in a thin elastic envelope, but, unlike the plant cells, they have no resistant cell wall to support the membrane; consequently, when they are placed in water they readily swell up and finally burst, thereby liberating the coloring matter of the cell, the haemoglobin, so that the water acquires a deep-red color. This is called laking," p. 137.

"Van Slyke, while studying acidosis, made a very careful study of the pH of blood, and found that the maximum normal range of variation of reaction in different individuals is indicated by pH 7.30-7.50. Under extreme abnormal conditions the pH may fall slightly below 7.0, or may rise as high as 7.8. With the former condition *coma* occurs, while with the latter *tetany* is generally present," p. 327.

The reviewer was also interested in the paragraph on the poisonous action of pure water, p. 148, though he does not feel sure that the harmful action of eating snow or ice is entirely an osmotic pressure phenomenon. There might be a temperature effect. It also seems probable to the reviewer that the author has over-emphasized the dangers of drinking distilled water.

Wilder D. Bancroft

Crystalline Form and Chemical Constitution. By A. E. H. Tutton. 23 × 15 cm; pp. xii + 252. London: Macmillan and Co., 1926. Price: \$3.60. The subject is treated under the general headings: introduction; the main facts of crystallography; isomorphism; improved methods of crystallographic research; the research on the alkali sulphates and selenates; the research on the hexahydrated double sulphates and selenates; general con-

clusions regarding isomorphism; parallel growths, overgrowths, and mixed crystals; isogonism, polymorphism, and polysymmetry; enantiomorphism and optical activity—quartz as a typical example; enantiomorphism and optical activity—tartaric acid as example; remarkable cases and conclusions concerning optical activity; liquid crystals; Fedorov's crystallochemical analysis; general conclusions.

The reviewer was much interested in the view recorded on p. 29, which differs considerably from the popular one. "In the simpler cases, such as those of binary compounds like the chlorides of sodium and potassium, NaCl and KCl, or those containing only three elements such as calcite, CaCO_3 , the arrangement of the atoms of the different chemical elements is directly given by the X-ray results, and the structure thus appears as if it were of atoms and not of molecules, although of course the molecules are really there, as they were deposited from the saturated solution as such. These simpler cases have become referred to, probably not very accurately or advisedly, as 'ionised crystal-structures.' Yet in the face-centred cube of either rock-salt or potassium chloride, and in the corresponding face-centred rhomb of calcite, four chemical molecules definitely go to compose this unit-cell of the space-lattice. But in the case of complicated compounds, such as those of organic substances like tartaric acid or naphthalene, what is directly revealed is the molecular arrangement, that of the space-lattice, the unit-cells of which are composed of one to four molecules; in the cases of both tartaric acid and naphthalene there are two chemical molecules, $\text{C}_4\text{H}_6\text{O}_6$ and C_{10}H_8 respectively, to each cell. The chemical molecule in these cases is very definitely present, and the exact way in which the two are arranged with respect to each other has been determined. Now as the molecule goes into the crystal with practically no change, the stereometric arrangement of its atoms, and its consequent chemical constitution, is a matter of immense importance, and if the arrangement of the atoms shows any elements of symmetry these must have an influence on, and indeed take part in, the crystal symmetry, and assist in determining the particular class of the system which is developed."

"The original principle, formulated by 'the father of crystallography,' the Abbé Haüy, in the year 1782, was that 'every single substance, definitely chemically constituted, possesses its own crystalline form.' This was intended further to mean that "the angles between the faces of this form are peculiar and special to the substance." We must add to this, from later knowledge, 'unless it be of cubic symmetry.' For the perfect symmetry of the cubic system itself determines the angles of the cubic forms, which are, therefore, invariable. We can also truthfully add, which substantiates Haüy even for cubic substances, 'and, whatever the symmetry, even if cubic, is endowed with its own crystallographic physical properties, such as crystal density, optical refraction, elasticity, and electrical constants.'

"The facts above stated between inverted commas are now established without fear of contradiction. Even if the substance be polymorphous, the two or more forms are unlike that or those of any other body," p. 5.

In 1812 Wollaston showed that the angles of such similar forms as calcite, siderite, and dolomite "were not identical, but differed quite appreciably, well beyond the possible experimental error of his [newly invented] goniometer. For instance, he gave for the rhombohedral angle of calcite $105^\circ 5'$, for that of dolomite $106^\circ 15'$, and that of chalybite $107^\circ 0'$, precisely the values accepted today after repeated remeasurement by several later crystallographers," p. 36.

"There can be no question whatever that to Wollaston belongs the credit of having not only discovered isomorphism, but of showing that outside the cubic system isomorphous substances possess their own exact form, with angles distinct from those of every other substance, even those of the same isomorphous series. It is high time that this credit were assigned to him," p. 37.

"Quite apart from the question of the strict interpretation of the term isomorphism, a result of immense importance to chemistry at once sprang from the magnificent work of Wollaston and Mitscherlich, largely owing to the fact that Berzelius, who was so interested in Mitscherlich, was the greatest living authority on the equivalents and atomic weights

of the elements. It was obvious that the substances which were shown to be isomorphous were chemically analogous, and it was usually the case that an isomorphous group was formed by the interchange of elements belonging to the same family group, or acting chemically similarly, that is, the different members of the isomorphous series were of similar chemical constitution, and only differed in having present in each case a different member of a family group of closely allied and similarly behaving chemical elements. Thus in the sulphate-selenate series, selenium, which is an element of the sulphur group, having similar combining power (valency) and forming the same type of compounds, replaces sulphur without immediately apparent change of crystal form. Now Berzelius, in studying the chemical relationships of all the elements known up to that time, had found great difficulty in fixing the atomic weights from the equivalents, and thereby defining their positions among the elements, of quite a number of elements, and not only indeed the rarer and more lately discovered ones. But here in the principle of isomorphism was a new ally, and most of these difficult cases were at once cleared up by the application of the new principle, the salts of these elements being found to be isomorphous with those of well-understood elements about whose positions there was no ambiguity. The elements which he thus correctly placed in position, and the atomic weights of which he was able to fix, were copper, cadmium, zinc, nickel, cobalt, iron, manganese, chromium, sulphur, selenium, and chlorine. Also the queer case of the ammonium salts, in which the base ammonium was known to replace potassium isomorphously, was eventually settled. For at this time the constitution and composition of ammonium was a matter of bitter controversy. It was finally shown that it was ammonia gas, nitrogen hydride, NH_3 , with an additional atom of hydrogen, namely, NH_4 , that acted as a radicle or group-entity in replacing an atom of potassium," p. 41.

"Specific chemical substitutions invoke localised changes in the crystal structure, one crystal-axial direction frequently suffering much more change than the others, indicating that the chemical atoms occupy definitely localised positions in the crystal unit, the space-lattice cell, and therefore in the crystal molecule (the chemical molecule as it exists in the solid crystal state) or molecules (four in the rhombic series of sulphates and selenates, confirmed by X-ray analysis, and probably two at most, and possibly only one, in the double salt series) which compose the 'cell.' The actual positions of the atoms thus definitely fixed have, long after this fact was first published by the author, since been revealed by means of X-rays, which, by reason of their wave-lengths being of the same order of dimensions as the atoms, are capable of reflection from or diffraction by the space-lattice-planes of atoms, at definite glancing angles for X-rays of specific ("monochromatic") wave-length, which enable the spacing of the planes to be calculated in absolute measure, and thence the unit cell dimensions and volumes," p. 128.

In overgrowths "there is also the important case of the triclinic plagioclase feldspars, albite the soda feldspar $\text{NaAlSi}_3\text{O}_8$, and anorthite the lime feldspar $\text{CaAl}_2\text{Si}_2\text{O}_8$, the former having the molecular volume 100.1 and the latter the molecular volume 101.5. Zonal growths of one of these on the other are very common, often taking the form, as seen in rock sections, of regular bands surrounding a nucleus; and these two feldspars are the end members of a whole series of plagioclase feldspars containing both soda and lime, but they are not truly different minerals, although they have been given distinctive names, such as oligoclase, andesine, and labradorite, but isomorphous mixtures in different proportions of the two well-defined mineral species albite and anorthite, with optical properties of a distinctive character. 'Solid Solution' is a term, first applied by van't Hoff, which has been given to such close mixtures of isomorphous compounds, although the term appears to the author to be no more satisfactory than the so-called 'liquid crystal' term is for the curious liquids with which Lehmann has made us so familiar. But if by "solid solution" the idea is merely conveyed that the physical properties alter continuously with the chemical constitution, then it accords with the facts as derived from the results of the latest investigations, including the use of X-rays," p. 143.

"Some very interesting further facts, however, have been derived from the prolonged researches on mixed crystals. If we take, for instance, the case of the rhombic series of

alkali sulphates and selenates, the volume constants and cell-edge dimensions of which are given on pages 94 and 95, it is found that the two end members of either group, the potassium and caesium salts, which in the progression according to atomic number of the alkali metal are the furthest apart in regard to the relative and absolute dimensions of the space-lattice cells, never form mixed crystals at all, nor even any parallel growths or overgrowths. But the intermediate rubidium salt will form mixed crystals with either the potassium or the caesium salt, but with some difficulty, however, and parallel growths readily, the differences in cell dimensions being less in these cases. On the other hand, the ammonium and rubidium salts, which have been shown to be remarkably isostructural, will form mixed crystals with the greatest ease, and in all proportions. These facts are not only due to the author's observations; they were quite independently observed and published by T. V. Barker and by G. Wulff of Moscow. There is thus the fullest confirmation of their truth. That the absolute dimensions of the cells, as well as the relative sizes, in the cases of the rubidium and ammonium salts of the same group, are nearly identical was proved by the X-ray analysis of the crystals supplied by the author to Sir William Bragg, in whose laboratory the analysis was carried out as already described," p. 145.

"The question that has agitated most of the workers on the subject of mixed crystals has been whether the two substances which mix in the crystalline condition do so in alternating layers of the two substances—a view advocated by Retgers—or as a much more intimate intermingling, to form a crystal with intermediate angles and physical properties, as of one single substance. This latter view has been held by Wulff, Barker, Gossner, from work on the silico-fluorides and stannofluorides of zinc and nickel, and the author," p. 146.

"The matter has eventually been settled by X-ray analysis. Two independent X-ray investigations were carried out by Vegard and Schjelderup with mixtures of the cubic alkali halides, potassium chloride KCl, potassium bromide KBr, and ammonium bromide NH_4Br , and by Rinne with the rhombohedral carbonates, the cubic haloid salts of lithium, sodium, potassium, rubidium, and caesium, and several mixtures of metals. In all cases the mixed crystals were found to reflect X-rays as single entities, the spectra being, not double as from two different structures, but single and as clearly defined as for a pure single substance. The atoms of the two substances are probably most intimately disseminated throughout the structure, in the proportions corresponding to the relative quantities of the two substances present," p. 147.

"Pasteur somewhat later made the further remarkable observation that when the spores of the ferment *Penicillium glaucum* are added to a solution of racemic acid containing a small quantity of phosphates, which would appear to be essential to the life of the organism, the dextro component of the molecular compound is devoured by the organism, while the laevo component is unacted upon so long as any dextro remains. Why this selection occurs is one of the mysteries of life, but the fact is a fortunate one for enabling the laevo variety to be isolated, and it was thus obtained practically pure by Pasteur," p. 202.

"Pasteur was born on December 27th, 1822, and in December 1922 a paper was presented to the Royal Society by Mr. W. T. Astbury describing the successful X-ray analysis of tartaric acid, carried out in Sir William Bragg's laboratory, fully confirming the work of Pasteur and affording a remarkable insight into the crystal structure of the two varieties. Two asymmetric molecules $\text{C}_4\text{H}_6\text{O}_6$ were found to be contained in the unit cell of the space-lattice. The expected spiral structure was revealed, and in fact two spirals are present of different winding, but not mirror-images of each other. One is in the interior of the molecule itself, being associated with the four carbon atoms of the centre of the molecule, which are situated at alternate corners of the oblique parallelepiped; it therefore remains permanent when the crystal is dissolved in water, and causes the dextro-gyratory optical activity of the solution of ordinary tartaric acid. The other is a twist caused by the necessity of fitting the molecules in their places, and is associated with the four hydroxyl groups; it is thus a peculiarity of the crystal structure only. Being of inverse sign to the other, laevo-gyratory in the case of ordinary tartaric acid, and more powerful in its effect on light, it imposes, in the net result of the two rotations, its sign on the rotation of the plane of polarisation by the crystals. The two molecules in the cell are of the same variety, definitely

either right (in ordinary tartaric acid) or left (in the laevo acid), and not of the two different varieties, so that there is no internal compensation. The three accompanying figures illustrate the results," p. 204.

"The best explanation yet advanced as to the nature of 'liquid crystals' is due to Bose, and is known as the 'Swarm Theory,' which he propounded in 1907. It is practically based on the fact already commented upon, that the molecules are always very extended ones. If two such elongated molecules approach each other within half their length, their free rotation is prevented in all directions except that of their length, so that a more or less parallel position is necessarily assumed. A bundle or 'swarm' of such molecules arranged parallel-wise will have the symmetry of a rotation figure, and behave somewhat like a uniaxial crystal. Now no biaxial interference figure in convergent polarised light has ever been observed with 'liquid crystals.' This is the more significant as the vast proportion of organic compounds crystallise in the three biaxial systems, and more than fifty substances are now known exhibiting the phenomena of 'liquid crystals.' Each individual swarm will be clear and transparent, but between the swarms light will be scattered and the observed turbidity thereby caused. The molecules in a single swarm, when confined in the thin film between the micro-slip and the cover-glass, will all be arranged end on, all parallel to themselves and perpendicular to the glass plates. They will take up this attitude very readily, owing to molecular cohesion, and it is in this position that they afford the uniaxial interference figure in convergent polarised light," p. 224.

It would thus appear that 'Liquid Crystals' are not really crystals at all, but a highly interesting intermediate form of matter, in which the molecules are no longer free to roll about as in a liquid, and yet are not arranged in a crystal structure but merely in bundles parallelwise, owing to their length or extended nature and shape, and partly aided in many cases, doubtless, by their viscosity. The unusual play of molecular forces between such large and extended molecules would, of course, also be a powerful factor in producing swarms. The long controversy, which raged between Vorländer, who stood out even more strongly than the late Prof. Lehmann himself (who, unfortunately, died last year, 1924), for a space-lattice crystal structure, and Tammann, who utterly negated the idea of anything but an ordinary emulsion, is thus apparently happily settled, the truth lying, as so often happens, between the two extremes," p. 226.

Wilder D. Bancroft

Collected Physical Papers. By Sir Jagadis Chunder Bose. 23 × 15 cm; pp. ix + 404. London and New York: Longmans, Green and Co., Price: 10 shillings. This book contains a collection of papers on physical subjects by the author. Bose was quite early in the field of investigation of the properties of Hertzian waves especially in connection with waves of short wave-length. He devised apparatus of quite small dimensions (compared with the large-scale apparatus of Hertz and Lodge) by which the optical properties of such waves could be demonstrated. A number of these papers were published in the Proceedings of the Royal Society of London from 1895 onwards. Bose has also made investigations on the response of plants to stimulation and has exercised considerable ingenuity in devising apparatus for such enquiries.

In connection with the apparatus for indicating the growth of plants, some doubt may be felt as to whether he has taken sufficient precautions against expansion due to temperature change. When a linear magnification of 50 million times is obtained, fluctuations due to temperature variations must be expected to become very evident.

However this may be, the papers (as Sir Joseph Thomson remarks in a foreword) make very agreeable reading, for the author is never dull. Moreover they have contributed largely to develop in India an interest in physical investigations. This work was that of a pioneer and the present rapid growth in physical science in India is to a large extent the outcome of that work. This volume is a fitting record of it.

A. W. Porter

VULCANIZATION OF RUBBER

BY NICHOLAS BACON

Introduction

Although vulcanized rubber articles have been in common use for more than three quarters of a century, nevertheless, the mechanism of the vulcanization process has never been satisfactorily explained. The rubber industry has recently grown to tremendous proportions. The introduction of organic accelerators has improved the physical properties of the rubber vulcanisate to such an extent that it has made possible the production of the modern automobile tire.

All the progress that the industry has made in improving the vulcanization process, has been brought about by empirical means. The "Edisonian" type of research that enabled Charles Goodyear to discover vulcanization is, even to this day, the system that is primarily employed in the rubber industry. Outside the classical work of C. O. Weber,¹ very few attempts have been made to study the subject of vulcanization from a systematic and scientific point of view. In studying the theories of vulcanization propounded by various investigators as outlined in a series of articles by Dubosc,² one immediately notices that the work of these investigators lacks coherence. Most of them draw sweeping generalizations from a small amount of experimental data confined to a narrow branch of the vulcanization problem, at the same time ignoring work performed in other fields of the same subject. Some of them seem to dodge the main issue of the problem. André Dubosc³ goes into elaborate detail in describing the formation of an active form of sulfur during the vulcanization process, but does not seem to be very much interested in what follows.

Things were in a rather chaotic condition until the advent of Wolfgang Ostwald⁴ in 1910. After surveying the results of the various investigators, and being an orthodox colloid chemist, he came to the conclusion that the available data were more in accord with a process of adsorption of sulfur by rubber than one in which sulfur entered into chemical combination. Ostwald's stand produced a beneficial effect in that it encouraged discussion and proved an incentive to further research on the subject of vulcanization. It helped rubber chemists to orient themselves so that the work undertaken was not done blindly. The issues of the subject were becoming plainly defined. Either chemical combination took place during the process, or it was simply a case of adsorption. From this one could deduce the possibility that it may be a combination of both.

⁴ *Kolloid-Z.*, 6, 136 (1910).

Before discussing any of the existing theories of vulcanization, it would be advisable to define some of the terms connected with vulcanization. When a rubber-sulfur mixture is subjected to a temperature of about 120°-150°C for some time, one notices a gradual change in the physical properties of the product. The temperature limits are not well defined and are changed radically by the presence of various accelerators. The lower the temperature the longer it takes the product to attain the desired changes in physical properties. The original object of vulcanization was to decrease the effect of temperature changes on the rubber, since the raw rubber becomes sticky when hot. Apart from this, there are other very noticeable temperature changes. If a piece of unvulcanized rubber is stretched and then chilled in ice water, it remains stretched. A piece of vulcanized rubber, for example an ordinary rubber band, snaps back after receiving the same treatment. A piece of partially vulcanized rubber, particularly if vulcanized with ultra-accelerators, may appear to have at room temperature about the same properties as the well-cured rubber band; but it will retract very slowly in ice water after being stretched. Both the partially vulcanized and the unvulcanized rubbers resume their original shape, or very nearly so, when they are brought back to room temperature.

On vulcanization, the raw rubber mixture undergoes other decided changes, becoming more resistant to solvents, stretching, abrasion, and the action of chemical agents, and also increasing in strength. These desirable changes in physical properties may be brought about also by the use of other agents. When raw rubber is treated with a dilute solution of sulfur chloride, it is not necessary to heat the product in order to attain the desirable physical properties characteristic of a vulcanized product. Raw rubber has been successfully vulcanized with *m*-dinitrobenzene,¹ trinitrobenzene, and with similar compounds; but these products proved to be of academic interest only, and never were able to assume the commercial importance allotted to the two classical methods mentioned above. The term vulcanization as commonly used in the rubber industry, is really confined to the process that causes a change in the physical properties of a raw rubber mixture which makes the product useful commercially. Vulcanization may, therefore, be defined for practical purposes as the change in physical properties due to the action of sulfur, or sulfur monochloride on rubber. A complete theory of vulcanization must, of course, include the somewhat similar changes in properties produced by oxygen, selenium, etc.; but it is simpler and wiser to consider the sulfur vulcanization first and later to see how far the conclusions are applicable generally.

The word "cure" is very often used synonymously with the term vulcanization, but really designates a particular stage in the process of vulcanization that yields a product of commercial value. If a product has acquired the desired physical properties, it is said to be "properly cured." If it has not reached that stage, it is said to be "undercured," and when it is heated too

¹ Stevens: *J. Soc. Chem. Ind.*, 36, 107 (1917).

long, it is said to be "overcured." During the process of vulcanization some of the sulfur becomes firmly attached to the rubber, whereas the remainder can be extracted easily by suitable solvents. The sulfur held in firm combination is called "combined sulfur," and the percentage of combined sulfur present, based on the original amount of raw rubber, is called "coefficient of vulcanization." One must bear in mind that the amount of combined sulfur present is not a measure of the degree of vulcanization. The attainment of the physical properties characteristic of a properly cured rubber mixture depends to a great extent on the presence of foreign ingredients such as accelerators. By the use of some organic accelerators it is possible to produce a vulcanized sample containing much less than half of one percent of combined sulfur. Some of the physical properties of this sample may be far superior to those of any properly cured sample, not containing any accelerator and having a combined sulfur content of over three percent. It is, of course, possible that a large part of this variation in properties may be due to the milder heating conditions.

The use of accelerators in the vulcanization of rubber is a very important phase of the rubber industry. They perform two functions:

In the first place, they reduce the amount of heat necessary for the process of vulcanization. Some of them are quite effective at temperatures much lower than those formerly used.

In the second place, their use improves the quality of the product obtained. The chief aim in the early development of the industry was to use accelerators for the purpose of shortening the time of cure. At present, accelerators are selected also on the basis of added physical properties.

Now that we understand what is meant by vulcanization we can proceed to discuss some of the theories that have been propounded to account for the peculiar phenomenon. Weber¹ was the first to formulate a theory that was substantiated by adequate scientific experimental data. The fact that a portion of the sulfur was taken up by the rubber in such a way as to be no longer extractable by solvents for sulfur, was regarded as evidence that chemical combination had taken place. Since the reaction was not accompanied by the evolution of hydrogen sulfide, Payen² had suggested that the process was one of addition and not substitution. The limit of combination of rubber with sulfur was shown to be reached in the formation of a compound having the empirical formula $C_{10}H_{16}S_2$ (polyprene disulfide). Weber regarded this as the highest member of a series of polyprene sulphides the lowest member of which was a compound represented by the formula $(C_{10}H_{16})_{10}S$ containing 2.29% sulfur. This was assumed to be the lowest compound because the properties of vulcanization first became apparent when the combined sulfur was present to the extent of 2 to 2.5%. Weber assumed that it was impossible to obtain any evidence of the formation of separate members of this series of compounds, since the alteration in properties from unvulcanized to vulcanized soft rubber and then to hard rubber was a gradual

¹ "The Chemistry of India Rubber," 91 (1902).

² *Compt. rend.*, 34, 2 (1852).

one, characterized by no sudden changes in any of its properties at any stage in the process.

While Weber's experiments indicated that the progress of vulcanization was accompanied by a chemical reaction, his explanation did not seem entirely adequate, since it was possible by use of accelerators, to vulcanize rubber with a smaller amount of sulfur than he had postulated for his smallest molecule $(C_{10}H_{18})_{10}S$. Weber's explanation accounts for the facts better than any other theory, but the main objection to it is that it is almost impossible to check it experimentally. By definition, it is assumed that the various members of the series of compounds formed are so closely related to each other in properties that it is naturally impossible to separate them.

A great many theories followed Weber's, but these may be regarded as the forerunners of the adsorption theory that was propounded by Wolfgang Ostwald in 1910. After considering all the results of previous workers, Wolfgang Ostwald sought to show that the available data were more in accord with a process of adsorption of sulfur by rubber than with one in which sulfur entered into chemical combination with the rubber. A very good discussion of the adsorption theory is found in Luff's book,¹ from which a good many of the facts have been taken. The chief facts on which his hypothesis was based were as follows:

- 1) In all vulcanized rubber there is present free sulfur which would not be expected if a chemical reaction were involved.
- 2) According to Höhn,² vulcanized rubber on sufficiently prolonged extraction could be freed entirely from sulfur.
- 3) The rubber always takes up sulfur in a purely additive manner.
- 4) A continuous series of addition products is formed, the first and last members of which have no definite stoichiometrical composition.
- 5) The amount of sulfur adsorbed by the rubber increases with the previous mechanical treatment. This could be explained by assuming rubber to consist of a two-phase system, the degree of dispersion of the disperse phase and hence the adsorptive capacity, being thus increased.
- 6) The capacity for taking up sulfur increases with rise in temperature and the temperature coefficient is more nearly in accord with an adsorption process.
- 7) The fixation of sulfur at a given temperature does not take place uniformly, as the breaks in Weber's curve show; this phenomenon is frequently met with in the adsorption of water by certain gels, for example silicic acid.
- 8) Adsorption proceeds in accordance with the exponential equation $x/m = kc^n$ where x is the weight of the adsorbed substance, m is the weight of the adsorbent, and k and n are constants.

The views put forward by Wolfgang Ostwald created a great deal of excitement and at the same time were a cause for further research which immediately established the inaccuracy of most of the facts upon which the adsorption theory was based.

¹ "The Chemistry of Rubber," 95 (1924).

² Gummi Z., 14, 17, 33 (1899).

With reference to the assumption that free sulfur is always present in vulcanized rubber, this is quite true with regard to the rubber heated with sulfur for a sufficient time to permit the characteristics of vulcanization to be assumed. It was shown, however, by Spence and Young¹ that on heating a mixture of 100 parts rubber, first extracted with acetone to remove resins, with 10 parts of sulfur for thirty hours at 135°C and ten hours at 155°C, respectively, no sulfur could be extracted on treatment with acetone.

Höhn's statements that all the sulfur could be extracted from vulcanized rubber failed to be verified by other workers. Stevens² cured a rubber mixture containing ten percent sulfur for thirty minutes at 145°C, and after nine weeks extraction with acetone, the sample still contained 1.55% sulfur. Other samples were treated in similar manner, but in all cases sulfur remained in the extracted sample even after nine weeks extraction.

In reference to the additive nature of the process, nobody ever questioned it after Weber's experiments showed the absence of hydrogen sulfide from the products of the reaction. The statements that none of the compounds formed by rubber-sulfur combination contained sulfur in stoichiometrical proportion was not in agreement with Weber's experiments, which showed that the highest limit of combination corresponded closely with the compound $C_{10}H_{16}S_2$. Spence and Young corroborated Weber's results by vulcanizing a rubber-sulfur mixture containing 63 parts rubber and 37 parts sulfur at 135°C for periods varying from one to thirty hours. At the end of 18½, 20, 25, and 30 hours the proportion of sulfur left in the residue after extraction of free sulfur was 31.75, 31.97, 31.91, 31.97 respectively. The samples after 20 hours vulcanization still contained about 4 percent free sulfur, so that the stopping of the reaction was not due to lack of sulfur.

The formation of an upper limit compound was further emphasized by Hinrichsen and Kindscher³ who heated rubber in cumene at 170°C with proportions of sulfur increasing to 400 percent, calculated on the rubber present. In all cases, a dark brown substance was obtained containing not more than 32 percent of combined sulfur.

With regard to the statement that mechanical working affected the rate of combination with sulfur, Weber⁴ had previously enunciated as a general principle that rubber containing a certain proportion of sulfur gave the same chemical result on vulcanization for a given time whether it had previously been subjected to mastication for a prolonged or normal period, although the physical properties might be widely different. Spence and Ward⁵ were able to corroborate these results. They found that the rate of combination of rubber with sulfur was the same whatever the mechanical treatment; but, in order to obtain products of equal tensile strength, it was necessary to vulcanize for a longer period in case of the over-milled sample than in the case of

¹ Kolloid-Z., 11, 28, (1912).

² J. Soc. Chem. Ind., 38, 195T (1919).

³ Kolloid-Z., 11, 191 (1912).

⁴ "The Chemistry of Rubber," 94 (1902).

⁵ Kolloid-Z., 11, 274 (1912).

the normally milled sample, and thus a higher coefficient of vulcanization was obtained.

According to Weber's results, the rate of fixation of sulfur at a given temperature was not uniform, and thus the breaks in the curve were held to support the adsorption theory. Of course, Weber himself suggested that the breaks in the curve might be interpreted as due to the formation of various chemical compounds, but finally decided that they had no such significance since these irregularities appeared at different places when vulcanization was carried out at different temperatures. He, therefore, concluded that they probably indicated a particular physical, rather than some definite chemical condition of the vulcanization product. Spence and Young repeated Weber's experiments, at the same time trying to eliminate all sources of error. They worked with acetone-extracted rubber so as to prevent the lack of uniformity that might result from the reaction of sulfur with non-caoutchouc substances proceeding at a different rate from that of the caoutchouc portion. Special care was also taken in reference to controlling the time of heating; and, in general, the technique governing the entire experiment was a vast improvement upon that of Weber's. Samples of a mixing of 90 parts rubber and 10 parts sulfur were heated at 135°C and various test samples were taken out at intervals. The combined sulfur was determined and the results obtained plotted against time of heating gave a smooth curve. A similar set of experiments was carried out at 155°C the results of which, likewise, produced a smooth curve when plotted.

The velocity coefficient k of the reaction was calculated from the equation $k = x/t$ where x is the percentage of sulfur entering into combination in time t . The temperature coefficient of the reaction velocity calculated from van't Hoff's equation was found to be 2.65 for ten degrees increase in temperature, a value agreeing with those generally obtained in case of a chemical reaction. Some experiments were performed at temperatures below 100°C and from this series, the temperature coefficient was calculated to be 2.84 which is within the limits characteristic of a chemical compound.

Further evidence in favor of a chemical combination is afforded by the experiments of Spence and Scott.¹ They found that when bromine reacts with vulcanized rubber, instead of combining in the ratio of four atoms of bromine for every $C_{10}H_{16}$, the resulting compound contains less bromine than required to form the tetrabromide, the balance being made up of the equivalent of sulfur.

Venable and Green² have shown that sulfur is quite soluble in rubber. This would naturally preclude the possibility of an adsorption complex between the sulfur and the rubber unless one made the unwarranted assumption that the sulfur suddenly crystallized out from solution and then became adsorbed on the rubber. This discussion of the theory of pure adsorption has brought forward an overwhelming amount of evidence in favor of the occurrence of a chemical reaction during the process of vulcanization.

¹ Kolloid-Z., 8, 304 (1911).

² J. Ind. Eng. Chem., 14, 319 (1922).

The controversy regarding the validity of the two classical theories naturally led to the formulation of theories that were to some extent a combination of both the chemical theory and the adsorption theory. Ostromuislenskii¹ considers vulcanization as a process in which only a small proportion of the rubber enters into combination with sulfur to form a compound in which the unchanged rubber is swollen or adsorbed. The reverse condition may equally hold in which the compound formed is adsorbed by the unchanged rubber.

Axelrod² has assumed a process of polymerization in order to account for the change in physical properties. He claims that vulcanization is a process in which there occurs a simultaneous "depolymerization" by means of heat and a "polymerization" due to the sulfur with simultaneous formation of a sulfur addition product. It is not clear just what the author means by the term "polymerization." The term may refer to the chemical process of polymerization or it may be regarded as the reverse of the effect noted when rubber is submitted to mechanical working.

An explanation postulating a process of chemical polymerization or physical aggregation, or a combination of the two, is not a foolish one, since we may regard caoutchouc itself as a polymerization product of isoprene. This transformation has changed a liquid, soluble in many organic solvents, into an elastic substance which is insoluble in many liquids capable of dissolving the parent hydrocarbon. It is therefore, possible that caoutchouc itself may be further polymerized to form a product that is still more resistant to solvents, and with more marked elastic properties. So far all the agents that have been known to induce this polymerization (vulcanization) have at the same time entered into some sort of a chemical combination. Another objection to this theory is the fact that, once the polymerization has been brought about, it is impossible to reverse the process by depolymerizing the vulcanisate chemically so as to yield the original raw rubber.

Kirchhof³ has put forward a modification of the above theory in which he assumes vulcanization to be a transformation of the rubber from an unstable to a relatively stable form, the chemical combination of sulfur being regarded as a subsidiary process.

Of course, there are many more theories on the subject of vulcanization than those outlined above. Many of them are simply modifications of various phases of the above theories; some of them dodge the subject of vulcanization by expending their energies in accounting for an active form of sulfur, while others are of no use as working hypotheses since they are based on assumptions that would be almost impossible to submit to experimental verification.

Before investigating the subject of vulcanization any further, one should remember some of the well-established facts regarding the process of vulcanization that must be explained by any workable theory.

¹ Luff: "The Chemistry of Rubber," 103 (1924).
